Hundreds of viruses that cause disease in humans are included in five orders: Bunyavirales, Herpesvirales, Mononegavirales, Nidovirales, and Picornavirales. The infections range in severity from completely asymptomatic to rapidly killing the human host. Individual viruses may cause several different diseases, and conversely, many viruses may cause the same disease, all of which complicates the understanding of viral disease in humans. For example, viruses that can cause encephalitis include HSV, many arboviruses, rabies virus, HIV, measles virus, and others. However, HSV also can cause pharyngitis, genital infection, conjunctivitis, and encephalitis. Viruses that are important human pathogens and the viral syndromes they cause are summarized in Table 64.1. Specific viral agents and their role in human disease are discussed in Chapter 65.

Laboratory Diagnosis

Designing a Clinical Virology Laboratory

The demand for clinical virology laboratory services has skyrocketed due to the introduction of virus-specific antiviral drugs; the commercial availability of reagents; the development of rapid diagnostic techniques using conventional methods such as enzyme immunoassays (EIAs); the ready availability of cell lines for virus detection in cell cultures; and the widespread use of nucleic acid amplification tests for detecting viral infections. Ironically, improved medical care, in the form of organ transplantation and immune suppression with cancer therapy, has resulted in an increased number of patients with viral disease. When these factors are considered along with the appearance of emerging and re-emerging viral pathogens that are threatening local and world populations (e.g., SARS, avian influenza, Crimean-Congo fever, Ebola, Lassa, Nipah, Rift Valley fever, Zika, African Swine fever), laboratory diagnosis of viral infection becomes far more important than in previous years.

When determining which virology tests to offer, each clinical laboratory should decide whether the test is required for the appropriate care of the patient population and whether techniques are available that provide an accurate, cost-effective test result. Viral diseases that require laboratory diagnosis include sexually transmitted diseases, diarrhea, respiratory disease in adults and children, aseptic

TABLE 64.1 Viral Syndromes and Common Viral Pathogens

Viral Syndrome	Viral Pathogens
Infants and Children	
Upper respiratory tract infection	Rhinovirus, coronavirus, parainfluenza, adenovirus, respiratory syncytial virus, influenza
Pharyngitis	Adenovirus, coxsackie A, herpes simplex virus, Epstein-Barr virus, rhinovirus, parainfluenza, influenza
Croup	Parainfluenza, respiratory syncytial virus, metapneumovirus
Bronchitis	Parainfluenza, respiratory syncytial virus, metapneumovirus
Bronchiolitis	Respiratory syncytial virus, parainfluenza, metapneumovirus
Pneumonia	Respiratory syncytial virus, adenovirus, influenza, parainfluenza
Gastroenteritis	Rotavirus, adenovirus 40-41, calicivirus, astrovirus
Congenital and neonatal disease	HSV-2, echovirus, and other enteroviruses, CMV, parvovirus B19, VZV, HIV, hepatitis viruses, Zika
Adults	
Upper respiratory tract infection	Rhinovirus, coronavirus, adenovirus, influenza, parainfluenza, Epstein-Barr virus
Pneumonia	Influenza, adenovirus, sin nombre virus (hantavirus), severe acute respiratory syndrome (SARS), coronavirus
Pleurodynia	Coxsackie B
Gastroenteritis	Noroviruses
Cervical cancer and certain types of oral cancer	Human papillomavirus
All Patients	
Parotitis	Mumps, parainfluenza
Myocarditis/pericarditis	Coxsackie B and echoviruses
Keratitis/conjunctivitis	Herpes simplex virus, VZV, adenovirus, enterovirus 70
Pleurodynia	Coxsackie B
Herpangina	Coxsackie A
Febrile illness with rash	Echoviruses and coxsackie viruses
Infectious mononucleosis	Epstein-Barr virus and CMV
Meningitis	Echoviruses and coxsackie viruses, mumps, lymphocytic choriomeningitis, HSV-2
Encephalitis	HSV-1, togaviruses, bunyaviruses, flaviviruses, rabies, enteroviruses, measles, HIV, JCV
Hepatitis	Hepatitis A, B, C, D (delta agent), E, and non-A, B, C, D, E
Hemorrhagic cystitis	Adenovirus, BK virus
Cutaneous infection with or without rash	HSV-1 and HSV-2, VZV, enteroviruses, measles, rubella, parvovirus B-19, human herpes virus 6 and 7, HPV, poxviruses, including smallpox, monkeypox, molluscum contagiosum, and orf
Hemorrhagic fever	Ebola, Marburg, Lassa, yellow fever, dengue, and other viruses
Generalized, no specific target organ	HIV-1, HIV-2, HTLV-1

CMV, Cytomegalovirus; *HIV,* human immunodeficiency virus; *HPV,* human papillomavirus; *HSV-1,* herpes simplex virus type 1; *HSV-2,* herpes simplex virus type 2; *HTLV-1,* human T-lymphotropic virus type 1; *JCV,* JC virus; *VZV,* varicella-zoster virus.

meningitis, arbovirus encephalitis, congenital diseases, hepatitis, and infections in immunocompromised individuals.

Laboratory scientists in a clinical virology laboratory must be familiar with cell culture, EIA, immunofluorescence methods, molecular methods (e.g., polymerase chain reaction [PCR] and next generation sequencing), and mass spectrometry (MS) in addition to other common laboratory techniques (Table 64.2). Large equipment needed for a full-service virology laboratory includes a laminar flow biologic safety cabinet (BSC), fluorescence microscope, inverted bright field microscope, refrigerated centrifuge, incubator, refrigerator and freezer, roller drum for holding cell culture tubes during incubation, and enzymes for molecular testing instrumentation (Figs. 64.5 to 64.7). In addition, many clinical laboratories are becoming more automated with high-throughput instruments and robotic fluid handlers. This trend in automation is likely to continue with the goal of streamlining workflow, decreasing turn-around times, and improving service offerings.

Standard precautions and Biosafety Level 2 (BSL-2) conditions are needed for community and most nonretroviral laboratories. Regulatory requirements include standard microbiologic practices, training in biosafety, protective clothing and gloves, limited access, and decontamination of all infectious waste.

Many viruses are too dangerous and should never be propagated in a BSL-2 laboratory because of the risk of accidental exposure and lack of effective therapies, including influenza H5N1, SARS coronavirus, hemorrhagic fever viruses, and smallpox. Specialized high-containment laboratories (BSL-3 and BSL-4) exist at government facilities and some academic institutions that are dedicated and equipped to work with such agents, but they are generally not routinely used for clinical diagnostic purposes.

Specimen Selection and Collection

General Principles

Specimen selection depends on the specific disease syndrome, viral agents suspected, and time of year. Selecting a specimen based on symptoms is confusing, because most viruses enter through the upper respiratory tract and infect tissues that may produce symptoms distant from the primary inoculation site. For example, aseptic meningitis, caused by infection with various types of enterovirus (EV), may be identified by detecting virus in the throat, on a rectal swab, or in cerebrospinal fluid (CSF) specimens. Pharyngitis and gastrointestinal symptoms may not be among the patient's complaints upon clinical presentation.

Specimen selection based on the suspected viral agent is also complicated by the fact that similar clinical syndromes can be caused by many different viruses. When specimens required for identification of a specific virus are collected without thorough consideration of other possible viral and nonviral agents, additional important etiologic agents may be missed.

Selection of the appropriate type of specimen is one of the keys to a correct test result. Selection should include the proper specimen source and the correct sample volume and timing of collection. This information should be reviewed institutionally on an annual basis and made available to clinicians.

Appropriate specimen selection dictates that the specimen type and suspected viruses should be included on the requisition. The laboratory should always be notified if rare agents representing a danger to laboratory workers are suspected (e.g., SARS coronavirus, H5N1 avian influenza virus, hemorrhagic fever viruses). Serum for serologic testing may be necessary, and some viral diseases are more common during specific months. Table 64.3 presents specimens for the diagnosis of viral diseases, noting trends in seasonality.

Specimens for the detection of virus should be collected as early as possible after the onset of symptomatic disease. Virus may no longer be present as early as 2 days after the appearance of symptoms. However, other factors, such as the patient's immune status or age, the type of virus, and the amount of systemic involvement, may play a role in the length of time viral shedding is evident, allowing effective laboratory detection. Certain viruses, such as West Nile virus, produce a brief, low viremia and undetectable levels at the onset of symptoms. Recommendations for collection of various specimens are summarized in this section.

In addition to the type of specimen and collection method, validated devices or containers can enhance the recovery and detection of the viral agent. Swab specimens should not contain chemicals or other compounds that may be toxic to cultured cells and therefore are unsuitable for viral specimen collection. Calcium alginate swabs interfere with nucleic acid-based tests, the recovery of some enveloped viruses, and fluorescent-antibody tests and therefore should not be used.

Throat, Nasopharyngeal Swab, or Aspirate

In general, nasopharyngeal aspirates are superior to throat or nasopharyngeal swabs for recovering viruses; however, swabs are considerably more convenient. This is because most respiratory viruses replicate in the ciliated epithelial cells of the posterior nasopharynx. Throat swabs are acceptable for the recovery of EVs, adenoviruses, and HSV and for use in highly sensitive nucleic acid amplification tests (NAATs) whereas nasopharyngeal swabs or aspirate specimens are preferred for the detection of RSV and influenza and parainfluenza viruses. Rhinovirus detection requires a nasal specimen. Throat specimens are collected with a dry, sterile swab by passing the swab over the inflamed, vesiculated, or purulent areas on the posterior pharynx. The swab should not be touched to the tongue, buccal mucosa, teeth, or gums. Swabs should be polyester, Dacron, or rayon with plastic or aluminum shafts. Calcium alginate impairs the recovery of enveloped viruses, interferes with fluorescent-antibody tests, and are inhibitory to some NAATs. Flocked swabs made from nylon fiber are designed to optimize specimen absorption and release of respiratory epithelial cells for direct fluorescent testing of respiratory viruses. Nasopharyngeal secretion specimens are collected by inserting a swab

TABLE 64.2 Diagnostic Methods for the Detection and Identification of Viruses

Virus	NAAT	Culture	Antigen	Antibody	Pathology	Comments
Adenoviruses	P	A	P	A	A	NAAT is the most sensitive and can be used to monitor viral load. Antigen assays may be used for ocular, enteric, or respiratory adenoviruses.
Arboviruses	P, SP	SP	A	P, SP	NA	NAAT and antibody testing are useful in acute infection. Culture requires BSL-3 or BSL-4. NAAT not available except for West Nile virus.
Coronaviruses (SARS-CoV, SARS-CoV-2, Middle Eastern respiratory syndrome [MERS])	P, SP	SP	SP	SP	NA	NAAT and antibody testing, SARS-CoV and MERS testing is only available in public health or research laboratories. SARS-CoV-2 testing is available as an Emergency Use Authorization method in most large laboratories.
Cytomegalovirus (CMV)	P	A	A	P	A	NAAT most sensitive and can be used to determine viral load. IgM screen for recent infection and IgG to determine immune status.
Enteroviruses and parechoviruses	P	A	NA	NA	NA	NAAT more sensitive, preferred for CNS infections.
Epstein Barr virus (EBV)	P	NA	A	P	A	Serology is the preferred test for primary infection. NAAT is useful for monitoring viral load.
Filoviruses (Ebola or Marburg), and arenaviruses (lymphocytic choriomeningitis virus [LCMV], Lassa virus [LASV], others)	SP	SP	SP	P, SP	SP	NAAT is recommended. BSL-4 required for culture, except for LCMV.
Hantaviruses	SP	SP	SP	P	NA	NAAT and serology equally useful. BSL-4 required for culture.
Hepatitis A virus	NA	NA	NA	P	NA	Serology is standard testing.
Hepatitis B virus	P	NA	P	P	NA	Serology is used for diagnosis and monitoring course of infection. NAAT is used to monitor therapy and for genotype determination.
Hepatitis C virus	P	NA	A	P	NA	Serology used for diagnosis. NAAT confirms active infection and monitoring therapy. Genotype determination can be used to identify drug regimen and duration of therapy.
Hepatitis D virus	P	NA	P	P	NA	Testing confined to reference laboratories.
Hepatitis E virus	P, SP	NA	NA	P	NA	Serology is the standard diagnostic test. NAAT is required for transplant patients.
Herpes simplex virus	P	NA	NA	A	NA	NAAT is preferred method, especially in CSF. Serology is used to determine immune status.
Human immunodeficiency virus (HIV)	P	SP	P	P	NA	Serology is primary diagnostic method. NAAT are used to guide therapy and monitor response.

TABLE 64.2 **Diagnostic Methods for the Detection and Identification of Viruses—cont'd**

Virus	NAAT	Culture	Antigen	Antibody	Pathology	Comments
Human T-cell lymphotropic virus (HTLV)	A	ND	NA	P	A	Serology is the primary diagnostic method. NAAT is useful when serology is indeterminate.
Influenza viruses	P	A	P	ND	ND	NAAT is the most sensitive. Serology is useful for epidemiological studies.
Noroviruses	P	NA	SP	NA	NA	NAAT is primarily recommended.
Parainfluenza viruses	P	A	P	NA	NA	NAAT is more sensitive and recommended.
Parvovirus B19	P	NA	SP	P	A	Serology is used in immunocompetent patients. NAAT is the test recommended in immunocompromised patients.
Rabies virus	SP	SP	SP	P	P, SP	Testing is completed in public health laboratories. NAAT and culture can be completed on saliva, CSF, and tissue. Serology is used to monitor antibody titers following vaccination.
Respiratory syncytial virus (RSV)	P	A	P	NA	NA	NAAT is the most sensitive. Rapid antigen testing may be useful in pediatric patients.
Rotaviruses	P	NA	P	NA	NA	Antigen testing has been routine; however, NAAT gastroenteritis panels are now more widely available.
Varicella zoster virus (VZV)	P	A	P	A	A	NAAT is the most sensitive. Serology is useful in determining immunity and can be used in CNS vasculopathy.

A, Alternative testing where the clinical utility may be limited to specific infections, clinical sample types, or other clinical indications; *BSL,* biosafety level; *CNS*, central nervous system; *NA*, test is not available, not generally used, or for research use only; *P*, preferred test for routine clinical diagnostics; *SARS*, severe acute respiratory syndrome; *SP*, testing is limited to public health laboratories or other specialized laboratory due to specialized testing or biosafety concerns.

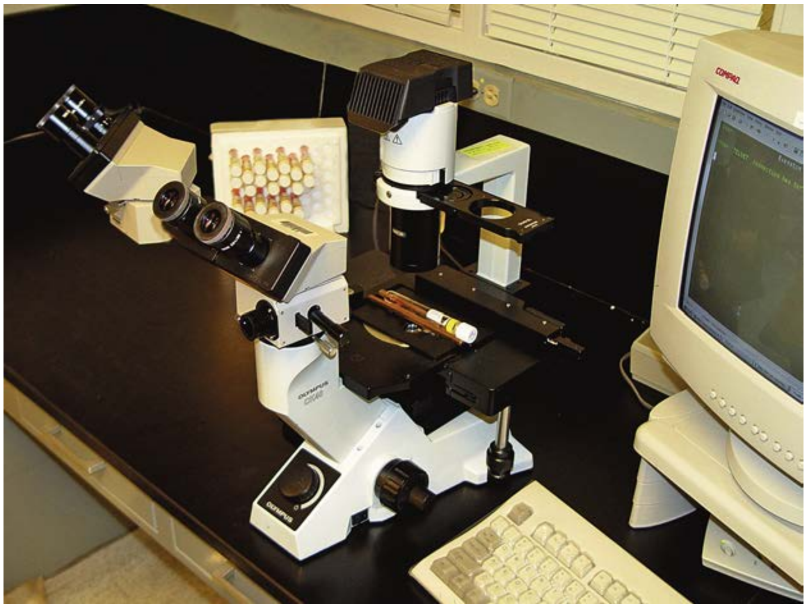
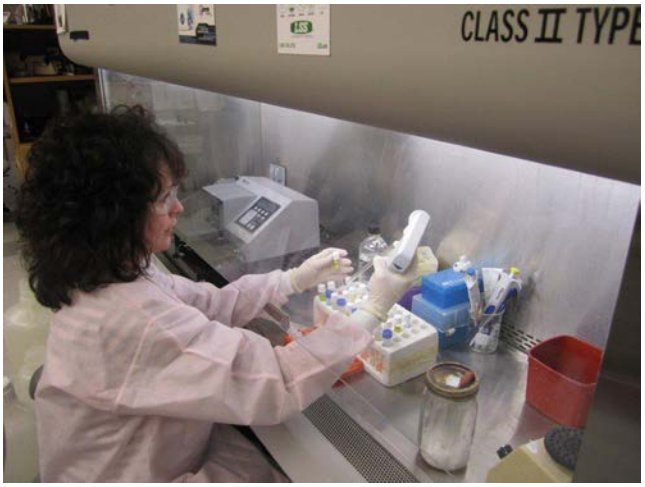
with a flexible shaft through the nostril into the nasopharynx or by washing and collecting the secretions by rinsing with a bulb syringe and 3 to 7 mL of buffered saline. The saline is squirted into the nose by squeezing the bulb and aspirated with small tubing that is inserted into the other nostril when the bulb or suction is released. Self-collected foam nasal swabs have demonstrated improved sensitivity over nasal washes for the detection of several viruses from respiratory viruses by NAAT.

Bronchial and Bronchoalveolar Washes

Washings and lavage fluid collected during bronchoscopy are excellent specimens for detecting viruses that infect the lower respiratory tract, especially influenza viruses and adenoviruses. Sputum may be acceptable for identification of viral pathogens using NAATs. Respiratory fluids or swabs in viral transport media should be centrifuged to remove contaminating materials. The supernatant can be used for culture. Further clarification may be completed using filtration. This process may result in the removal of virus infected cells and reduce the recovery of viral agents from the sample. It is not necessary to remove contamination in samples for antigen and nucleic acid testing.



• **Fig. 64.6** Inverted microscope used to examine cell monolayers growing attached to the inside surface beneath the liquid medium. Note that the objective is under the glass test tube, facilitating observation of the cell monolayer.



• **Fig. 64.7** Class II biologic safety cabinet used in a clinical virology laboratory.

Rectal Swabs and Stool Specimens

Stool and rectal swabs of fecal specimens are used to detect rotavirus, enteric adenoviruses (serotypes 40 and 41), and EVs. Many agents of viral gastroenteritis do not grow in cell culture and require antigen or NAAT for detection. In general, stool specimens are preferable to rectal swabs and should be required for rotavirus and enteric adenovirus testing. Rectal swabs are acceptable for detecting EVs in patients suspected of having an enteroviral disease, such as aseptic meningitis. The rectal swab is inserted 3 to 5 cm into the rectum and rotated against the mucosa to obtain feces. The swab should then be placed in appropriate transport media. A stool sample is preferred over a rectal swab because of the potential for decreased viral recovery from a small sample size. Five to 10 mL of freshly passed diarrheal stool or stool collected in a diaper from young infants is sufficient and preferred for rotavirus and enteric adenovirus detection.

Due to bacterial contamination of stool, centrifugation, filtration, or both are necessary for cell cultures for the recovery of viral agents.

Urine

CMV, mumps, rubella, and measles viruses, polyomaviruses, and adenoviruses can all be detected in urine, though these viruses are often shed intermittently or in low numbers. Viral recovery may be increased by processing multiple (two to three) specimens in parallel. Improved recovery results with a minimum specimen volume of 10 mL. The urine pH and contaminating bacteria may interfere with viral replication. Virus recovery in cell culture is improved by centrifugation or filtering to remove contaminants and neutralizing the pH with a 7.5% solution of sodium bicarbonate or diluting the sample with viral transport media. Ambient storage of urine should be minimized for NAAT. Nucleic acids are rapidly degraded in urine due to the low pH and high urea content. Extraction of nucleic acids is required prior to testing to prevent inhibition by additional substances commonly found in urine samples.

Skin and Mucous Membrane Lesions

EVs, HSV, VZV, and in rare cases CMV or pox viruses can be detected in vesicular lesions of the skin and mucous membranes. Once the vesicle has ulcerated or crusted, detection of the virus is difficult using culture, antigen, or NAAT.

Collection of fluid specimens from vesicles can be completed using a capillary pipette, syringe, or swab placed in viral transport media. A tuberculin syringe can be used to

[a]Direct fluorescent antibody studies are available for herpes simplex virus and varicella-zoster virus.

Specimens indicated beside specific viruses should be obtained if that specific virus is suspected (++++, most appropriate; +, least appropriate).

CSF, Cerebrospinal fluid; *F,* fall; *HIV,* human immunodeficiency virus; *S,* summer; *SARS,* severe acute respiratory syndrome; *SP,* spring; *W,* winter; *Y,* year-round.

aspirate fluid from the vesicle. The needle is flushed with a viral transport medium prior to aspiration. Cleaning the area with an antiseptic such as an iodophor or alcohol may inactivate the virus. Antisepsis should therefore be performed after the aspiration of the sample, If the sample is collected using a swab, the vesicle should be unroofed (remove the crust) with a sterile needle or scalpel. The swab should be rolled over the base and margin of the lesion to collect virally infected epithelial cells and placed in viral transport media. Caution should be taken to not cause bleeding, as antibodies present in the blood may neutralize the virus interfering with cultivation. Samples may be used for culture, antigen, or NAAT.

Sterile Body Fluids Other Than Blood

Sterile body fluids, especially CSF and pericardial and pleural fluids, may contain EVs, HSV, VZV, influenza viruses, or

CMV. These specimens are collected aseptically by the physician and sent to the laboratory for processing. CSF samples collected by lumbar puncture for NAAT should not be centrifuged prior to nucleic acid extraction. Extraction should be completed prior to testing to eliminate antibodies, proteins, and other potential inhibitors of molecular amplification enzymes. CSF and other sterile body fluids are not diluted with viral transport media as it may cause false negative results. In addition, fluid specimens contaminated with blood may inhibit viral cultivation due to the presence of antibodies.

Viral infections may occur during pregnancy that may cause serious disease in the fetus or newborn. Amniotic fluid is collected by amniocentesis. NAAT is the most common method used for accurate diagnosis of congenital CMV infections, VZV, or parvovirus B19. If testing is delayed, the nucleic acids should be extracted and refrigerated up to 48 hours or frozen at –70°C. The samples may also be used for culture, but sensitivity is significantly lower than NAAT.

Blood serum, plasma, purified peripheral blood leukocytes, and whole blood may be used for viral detection. Viral culture of blood is used primarily to detect CMV; however, HSV, VZV, EVs, and adenovirus occasionally may be encountered. CMV viremia is associated with peripheral blood leukocytes. Five to ten milliliters of anticoagulated blood collected in a whole blood tube is needed. Heparinized or ethylenediaminetetraacetic acid (EDTA) anticoagulated blood is acceptable for CMV detection. Leukocyte fractionation should occur within 8 hours of collection. Density gradient methods that include centrifugation are commercially available for the removal of erythrocytes that would be inhibitory to viral replication in culture.

EDTA and citrated blood should be used for samples collected for nucleic acid testing, because other anticoagulants may interfere with the enzyme functions required for NAATs. Serum may be used for serologic tests and nucleic acid assays. If whole blood is used for NAAT, heme and the metabolic precursors for heme must be removed prior to testing. Many commercial extraction protocols include the reagents and processes to remove these components.

Dried Blood Spots

Dried blood samples can be used for the detection of viral antibodies as well as NAAT. Samples can be collected from a capillary finger stick and air dried for 2 hours. Once dried, the sample is placed in a hermetically sealed bag or container containing a desiccant to avoid exposure to moisture and prevent the growth of any contaminating bacteria. Samples may be transported at room temperature, refrigerated, or frozen at –20°C or lower.

Bone Marrow

Bone marrow for virus detection should be added to a sterile tube with anticoagulant. Heparin or EDTA anticoagulants are acceptable for culture. EDTA or ACD (anticoagulant citrate dextrose solution) should be used if the specimen is intended for nucleic acid testing. Specimens are collected by aspiration and should be processed for the fractionation of leukocytes as soon as possible. Bone marrow specimens for NAAT may be refrigerated if processing is delayed. Freezing and thawing will result in cell lysis releasing heme and other cellular components that are inhibitory to NAATs. Nucleic acids must be extracted prior to NAAT methods.

Tissue

Tissue specimens are especially useful for detecting viruses that commonly infect the lungs (CMV, influenza virus, adenovirus, sin nombre virus), brain (HSV), and gastrointestinal tract (CMV). Other viruses may be identified from the liver, lymph nodes, kidney, spleen, or cardiac tissue. Specimens are collected during surgical procedures. Fresh tissue is required for culture and is preferred for nucleic acid assays, but formalin-fixed and paraffin-embedded tissues may be used after removal of the paraffin (deparaffinization) and extraction. The stability of nucleic acids in tissue varies with viral and tissue type. Samples should be transported to the laboratory on wet ice or frozen. Tissue should be minced and digested with proteolytic enzymes prior to nucleic acid extraction. Fresh tissue for viral cultivation should be homogenized in viral transport media and centrifuged to remove unwanted cellular debris. The supernatant is then used to inoculate the viral culture.

Genital Specimens

Genital specimens often are required for detection of HSV and HPV. Genital lesions or ulcerations should be collected and processed as previously described for skin lesions and placed in appropriate viral transport media. Cervical specimens may be collected using a swab or brush and placed in viral transport media. Most manufactured endocervical or liquid-based cytology devices are appropriate for nucleic acid testing. Following the manufacturer's recommended protocols is essential when processing such specimens. Anal specimens should be collected using a Dacron swab moistened with saline and transported in liquid cytology media for the detection of HPV.

Oral

Some viral infections are transmitted in oral secretions and can be detected from oral mucosal cells, saliva, glandular duct salvia, or oral mucosal transudates**.** These samples can be used for culture or NAATs. Salivary gland fluid may also be used for the detection of viral antibodies including secretory IgA, IgM, and IgG. Samples are collected using a sputum collection device, swab, or spatula and placed in transport media.

Serum for Antibody Testing

Acute and convalescent serum specimens may be needed to detect antibody to specific viruses. Acute specimens should be collected as soon as possible after the appearance of symptoms. The convalescent specimen is collected a minimum of 2 to 3 weeks after the acute specimen. In both cases, an appropriate specimen is 3 to 5 mL of serum collected by venipuncture. Serum can be stored for hours or days at 4°C or for weeks or months at −20°C or lower before testing. Testing for virus-specific IgM should be completed before freezing whenever possible, because IgM may form insoluble aggregates upon thawing, producing a false-negative result.

Specimen Transport and Storage

Ideally all specimens collected for detection of virus should be processed immediately. Specimens for viral isolation should not be allowed to sit at room or higher temperature. Specimens should be kept cool (4°C) and immediately transported to the laboratory. If a delay in transport is unavoidable, the specimen should be refrigerated, not frozen, until processed. Every attempt should be made to process the specimen within 12 to 24 hours of collection. Under unusual circumstances, specimens may need to be held for several days before processing and should be stored based on specimen type as previously indicated in this chapter.

If a commercial kit is used for viral identification (e.g., nucleic acid testing), the specimens should be transported and stored according to the manufacturer's instructions.

Commercially prepared transport media are useful for maintaining viral stability. They are used to transport small volumes of fluid specimens, small tissues and scrapings, and swab specimens, especially when contamination with microbial flora is expected. Transport media contain protein (e.g., serum, albumin, or gelatin) to stabilize the viral agents and antimicrobials to prevent overgrowth of bacteria and fungi. Penicillin (500 units/mL) and streptomycin (500 to 1000 μg/mL) have been used traditionally; however, a more potent mixture is composed of vancomycin (20 μg/mL), gentamicin (50 μg/mL), and amphotericin (10 μg/mL). If serum is added as the protein source, fetal calf serum is recommended, because it is less likely to contain inhibitors, such as antibodies. Examples of successful transport media include Stuart's medium; Amie's medium; Leibovitz-Emory medium; Hanks' balanced salt solution (HBSS); Eagle's tissue culture medium; and the commercially available M4, M5, and universal transport media. Respiratory and rectal and stool specimens can be maintained in modified Stuart's medium, modified HBSS, or Leibovitz-Emory medium containing antimicrobials.

Specimen Processing

General Principles

Specimens for viral culture should be processed immediately upon receipt in the laboratory. This may be accomplished by combining bacteriology and virology processing responsibilities. Although the threat of cell culture contamination in the past dictated separation of virology procedures, the addition of broad-spectrum antimicrobials to cell cultures has significantly reduced the possibility of cross-contamination with bacteria and fungi. In most laboratories, processing with other microbiology specimens allows viral cultures to be processed 7 days a week. If delays must occur, specimens should be stored in a viral transport medium at 4°C as described previously. Delay in the processing of fluid specimens requires dilution in a transport medium (1:2 to 1:5) before storage.

In addition to patient identification and demographics, each specimen for virus isolation or identification should be accompanied by a requisition that provides (1) the source of the specimen; (2) the clinical history or viruses suspected; and (3) the date and time of specimen collection. If this information is not available, a call for additional details should be made to the requesting physician or to the person caring for the patient.

Viral specimens should be processed in a BSL-2 or BSL-3 dependent on suspected viral agent. (Fig. 64.7). This protects specimens from contamination by the processing technologist and protects those in the laboratory from infectious aerosols created when specimens are manipulated. When patient cell cultures are manipulated, such as during inoculation or feeding (exchange of cell culture medium), only one patient sample or series of cell culture tubes should be open at one time. Aerosols and microsplashes contribute to cross-contamination of cultures, especially during viral respiratory season when a high percentage of specimens are positive for influenza virus, RSV, and other viruses.

Processing virology specimens for culture is not complicated (Table 64.4). In general, any primary specimen or swab specimen that may be contaminated with bacteria or fungi should be added to a viral transport medium. Normally sterile body fluids can be inoculated directly to cell culture. Sterile body fluid specimens, whether in viral transport medium or not, should be vortexed immediately before inoculation to break up virus-containing cells and resuspend the inoculum. Adding sterile glass beads to the transport medium helps break up cell clumps and release virus from cell aggregates. This may not be necessary, because some commercially available mediums already contain beads. Grossly contaminated or potentially toxic specimens, such as minced or ground tissue, can be centrifuged (1000 × *g* for 15 minutes) and the virus-containing supernatant may be used as the inoculum. Each viral cell culture tube should be inoculated with 200 to 400 μL of specimen. If insufficient specimen is available, the specimen obtained should be diluted with a viral transport medium to increase the volume. Excess specimen can be stored at −70°C in the event the initial culture is contaminated. A set of uninoculated cultures should be maintained simultaneously for continual monitoring of sterility and contamination throughout the process.

Contaminated specimens can be reprocessed with an antibiotic-containing viral transport medium if they were not originally handled in this manner, or they can be filtered using a disposable 0.22 to 0.45 μm filter, and the filtrate can be recultured. In practice, virus is rarely detected in culture from most specimens requiring reprocessing. When these specimens are processed, the specimen should be allowed to adsorb in an incubator at 35°C to 37°C for 30 to 60 minutes; 1 to 1.5 mL of maintenance medium should be added, and the tubes returned to the incubator, preferably

in a roller rack in a rotating drum. Blood for viral culture requires special processing to isolate leukocytes, followed by inoculation into cell culture tubes (Evolve Procedure 64.1). Rapid shell vial cell cultures are used to detect many viruses. (Handling and examination of cell cultures after inoculation with specimen are discussed later in this chapter.)

Specimens used for NAAT may need to be processed and the extraction of nucleic acids may be necessary prior to storage to prevent degradation of nucleic acids as previously described in this chapter.

Processing Based on Requests for Specific Viruses

Arboviruses

Arboviruses are a group of viruses that are transmitted by mosquitoes, ticks, or other arthropods resulting in a spectrum of disease, from mild viral syndrome to encephalitis. There are several viral antigen tests available for use in the field in endemic areas. Positive field tests should be confirmed using either serologic or NAATs. Diagnosis of arbovirus encephalitis, such as Eastern, Western, Venezuelan, St. Louis, and California encephalitis; and La Crosse, West Nile, and Zika virus infection requires detection of virus-specific IgM antibody in serum or a rise in IgG antibody titer in paired sera. Detection of virus-specific IgM in CSF is available for most agents. Culture of arboviruses for diagnostic purposes is not practical.

Several types of NAAT for some agents are available through state public health laboratories, specialized reference and academic laboratory. NAATs may be less sensitive than serodiagnosis because the virus and the viral nucleic acid are only detectable for brief periods during infection. In addition, the efficiency of the extraction and purification of the target RNA can significantly impact the sensitivity of the assay.

Cytomegalovirus

CMV can be detected in clinical specimens using conventional cell culture, shell vial assay, antigenemia immunoassay, or NAAT methods. CMV produces **cytopathic effects (CPEs)** in diploid fibroblast cells in 3 to 28 days, averaging

7 days. Sensitivity of the CMV shell vial assay is equivalent to conventional cell culture, and results are available within 16 hours. The antigenemia immunoassay uses monoclonal antibody in an indirect immunoperoxidase enzymatic reaction or indirect immunofluorescent stain to detect CMV protein (pp65) in peripheral blood leukocytes. The antigenemia assay requires 2 to 4 hours and includes the sedimentation and separation of leukocytes, counting of leukocytes, and a standardized density smear preparation, followed by staining and counting of infected (fluorescing) cells (Evolve Procedure 64.2). Results are reported as the number of positive leukocytes per total number of leukocytes in the smear. Several quantitative CMV PCR testing platforms are also available for detection and quantitation of CMV viremia. Molecular assays have replaced the antigenemia assay in some laboratories. The quantitation of CMV-DNA is the best predictor of CMV disease. It is essential in the diagnosis of disease in immunocompromised patients. CMV DNA can be detected in whole blood, peripheral blood leukocytes, plasma, and serum by PCR. Qualitative assays may also be useful in unique cases including the use of saliva, urine, tissue, amniotic fluid, or fetal blood for the diagnosis of congenital infection and aqueous or vitreous humor for the detection of CMV retinitis. A negative qualitative result is highly predictive of the absence of systemic CMV disease or tissue-invasive infection. Although there seems to be some agreement between antigenemia assays and quantitative CMV DNA assays, there are differences because the assays measure different features of the virus. Because of the variation between samples, patient populations, and thresholds for predicting disease in different laboratories, it is important for the laboratory to monitor the relative changes in a specific patient using the same assay and specimen type over time. Molecular methods are essential in establishing criteria for patients developing disease, monitoring therapy, and predicting viral resistance.

Enteroviruses and Parechoviruses

Molecular sequencing of viruses has effectively redefined the organization and classification of viruses traditionally included in this group. Some of the viruses initially included in the EVs have now been reclassified as parechovirus (PeV). Both the EVs and PeVs are capable of causing many localized and systemic infections. These viruses can be detected using conventional cell culture and NAATs. A combination of human and primate cell lines are used to isolate EV and PeV viruses, although no single cell line supports the growth of all viruses. To reduce waste and provide availability when needed, frozen "ready cells" (Diagnostic Hybrids, Athens, OH) may be used. Ready cells may be stored for up to 5 months and demonstrate comparable results as fresh cells. Presumptive diagnosis is based on CPEs. Confirmation or definitive diagnosis is accomplished using commercially available FA stains.

NAAT is the preferred method for the detection and diagnosis of infections with EV and PeV. Some viruses fail to grow in cell culture or propagation methods are unknown. In addition, NAAT detection for EVs has improved patient care, demonstrating a clear correlation of improved outcomes when comparing time to result and length of hospital stays. This is significant in cases of EV septic meningitis. There are FDA approved real-time assays available for the detection of EV in CSF for the detection of meningitis, including the Cepheid Xpert and the BioFire Meningitis/Encephalitis (ME) Panel.

Epstein-Barr Virus

Serologic tests are useful in the diagnosis of Epstein-Barr virus (EBV)–associated diseases, including infectious mononucleosis, and remains the method of choice. There are a variety of assays available that differ in the methodology, antigens, and antibody isotype included in the test. Isolation of EBV (in cultured B lymphocytes) is not routinely performed in clinical laboratories. Cellular tropism of EBV in the peripheral blood in patients with high, persistent viral loads are being examined using cell phenotyping and flow cytometry. These assays are currently not available in routine diagnostic laboratories.

NAAT is used for quantitative direct detection of EBV DNA. The World Health Organization has approved an international standard for EBV which is a whole virus preparation produced by the National Institute for Biological Standards and Controls (United Kingdom). This standard should be extracted in the same matrix as the clinical sample simultaneously to properly quantitate the viral DNA in the patient sample. Although the creation of an international standard has reduced the variability associated with the use of molecular methods in the diagnosis of EBV infections, other limitations remain including the variability in commercial reagents and gene targets used in the assays. Patient results with low viremia tend to show the greatest variation in results. It is therefore recommended that viral DNA values should be at least threefold to be considered significant to changes in viral replication. If the assay values are very close or near the limit of detection of the specific assay, viral load changes may only be significant if greater than 5-fold differences are noted. Extraction, contamination, and inhibition controls should also be included in the assay along with the EBV standard.

Hepatitis Viruses

Disease or asymptomatic carriage caused by hepatitis A, B, C, D, and E viruses is detected using serology, antigen detection, or NAAT. Even though hepatitis viruses are not routinely cultured, a variety of diagnostic tests are available for the detection of antibody and antigen. Hepatitis A, usually transmitted through contaminated food and water, is diagnosed by screening for the IgM antibody using serologic methods. HAV RNA can be detected in blood and stool and is useful in the diagnosis of early infections especially in cases with questionable serologic results. Hepatitis B produces acute and chronic infection and is associated with hepatocellular carcinoma; it is transmitted parenterally and by tattooing, acupuncture, sexual contact, and perinatal infection.

Several HBV-specific antigens can be detected in a patient during infection. The diagnosis of hepatitis B infection uses a combination of antigen and antibody detection and NAAT. Serologic diagnosis of hepatitis B infection is made through the quantitation of antibody that includes the antibody to the surface, core, and e antigens. The first marker to appear in acute infection is the hepatitis B surface antigen (HBsAg); as the infection resolves, HBsAg disappears and hepatitis B surface antibody (HBsAb) appears. NAAT are used to quantify HBV DNA to evaluate infections and monitor patients with chronic infections during treatment. In addition, there are patients who are infected with immune escape mutants that do not test positive by serological methods requiring HBV DNA testing to exclude low-level carrier states. Molecular methods are used to determine HBV DNA levels and to assist in establishing the stage of disease as well as monitoring patients on anti-viral therapy.

Hepatitis C is an RNA virus transmitted by blood transfusion, intravenous drug abuse, hemodialysis, and contaminated instruments, such as body piercing and tattooing devices. HCV infection becomes chronic in more than 80% of patients. The diagnosis is typically made by antibody detection followed by HCV RNA NAAT to determine the status of viral replication. The detection of HCV viral RNA is the primary determining factor to diagnose chronic infection. HCV RNA can also be measured quantitatively by PCR to assess the patient's response to antiviral therapies. HDV infection can be detected using serologic screening assays. A positive result may indicate acute or chronic infection and should be followed by an HDV RNA test. HEV RNA detection and quantification by PCR is the gold standard for the diagnosis of acute infection.

Herpes Simplex and Herpes B Virus

HSV type 1 and 2 cause a variety of infections including gingivostomatitis, fever, oral lesions, genital lesions, and lymphadenopathy. Herpes B virus is very similar to HSV in terms of structure, morphology, and viral replication and can cause serious illness including myelitis and encephalitis with a mortality rate of greater than 70% if left untreated. HSV grows rapidly in most cell lines. MRC-5 or mink lung fibroblast cell lines are recommended, along with a continuous cell line such as A-549. Ready cells, as previously described, are also available for the cultivation of herpes viruses. Fifty percent of genital HSV isolates are detected within 24 hours and 100% within 3 to 5 days. Cultures should be examined daily and finalized if negative after 5 days of incubation. The enzyme-linked viral-induced system (ELVIS; Diagnostic Hybrids, Athens, OH) is a special shell vial system available for detection of HSV in 24 hours. When the cells become infected with HSV, they accumulate beta-galactosidase. After incubation, the shell vial is fixed and stained with substrate for beta-galactosidase, resulting in a visible blue color change that can be viewed using an inverted microscope. This technique is described in more detail later in this chapter. In addition, type-specific serology tests, such as HerpeSelect (Focus Diagnostics, Cypress, CA) are also available.

NAAT are the most sensitive methods for the detection of HSV. There are a variety of qualitative and quantitative FDA approved molecular HSV assays available. Molecular detection is extremely useful in the detection of virus in CSF. Viral quantification can be used to monitor response to antiviral therapy in severe infections such as HSV encephalitis and neonatal infections. Molecular methods for the detection of HSV are preferentially used in many laboratories; however, conventional culture remains useful in the diagnosis of herpes in mucocutaneous, genital, and ocular lesions.

Human Immunodeficiency Virus and Other Retroviruses

HIV type 1 (HIV-1) is detected using serologic methods (i.e., antibody or antigen) and molecular methods (reverse transcriptase PCR [RT-PCR]). HIV-1 enzyme-linked immunosorbent assay (ELISA) antibody tests also detect antibody to HIV type 2 (HIV-2). The ELISA screening test is no longer confirmed with an HIV-1–specific Western blot test or with an ELISA for HIV-2 followed by an HIV-2–specific Western blot test. Recently infected patients may test as a false negative or indeterminate result using these methods. In addition, HIV-2 may be misidentified as HIV-1 in serologic methods. The current recommendation is to test for HIV-1 and HIV-2 using a combination anti-HIV-1 and HIV-2 and HIV-1 p24 antigen immunoassay. All reactive specimens should then be tested using an immunoassay that specifically differentiates HIV-1 and HIV-2. Samples that are reactive on the initial screening assay but are negative or indeterminate on the follow-up immunoassay are then subjected to nucleic acid-based testing for resolution. Recently infected patients who have not seroconverted or newborn babies with maternal antibody can be identified as HIV-infected using sensitive RT-PCR assays. HIV infection can also be monitored in those receiving antiviral therapy using quantitative molecular testing with plasma specimens, CD4+ T-lymphocyte determinations, and an antiretroviral resistance assay. Successful antiviral therapy should reduce the HIV plasma viral load to undetectable levels. These assays can also be used as prognostic indicators and to determine infectiousness.

Rapid point of care HIV immunoassays are not available for use following occupational blood or body fluid exposure or for pregnant women during labor when HIV status is unknown. These assays are either immunoconcentration methods or lateral flow assays. Home testing systems include the OraQuick in-home HIV test (OraSure Technologies, Bethlehem, PA). The test provides results within 20 minutes using an oral fluid sample. A positive result does not indicate definitive infection with HIV. CDC recommends early detection and testing by qualified personnel for the management of infection and appropriate follow-up testing. Home testing does not replace professional diagnosis and patient care.

Human lymphotropic viruses type 1 (HTLV-1) and type 2 (HTLV-2) are associated with very different disease presentations. HTLV-1 is associated with the development of adult T-cell leukemia/lymphoma (ATLL) and myelopathy/tropical spastic paraparesis (HAM/TSP), whereas HTLV-2 has not been definitively associated with malignancies (however, it has been associated with a neurological disease that resembles HAM/TSP with a slower progression and milder disease). HTLV-3 and HTLV-4 have been identified in a few individuals residing in Cameroon and has not spread locally or globally. NAAT are the preferred method for the determination of infection status, confirmation of serologic results, identifying tissue distribution, and distinguishing the different HTLV viral groups. All blood donors and patients with relevant clinical signs and symptoms should be screened for antibodies to HTLV-1 and HTLV-2. Western Blot is still utilized as a confirmatory test following a positive test for HTLV ½ by serological screening immunoassays. If the Western Blot is indeterminant or untypeable based on viral glycoproteins, then peripheral blood mononuclear cells should be completed using type-specific PCR.

Influenza A and B Viruses

Influenza A and B viruses can be detected using conventional cell culture, shell vial culture, membrane EIA, immunochromatographic assays, fluoroimmunoassays, indirect and direct staining of respiratory tract secretions using FA methods (Fig. 64.8), and RT-PCR. PMK cells demonstrate improved detection compared with other cell lines. The median time to detection, using hemadsorption at day 2 or 3, is approximately 3 days. FA staining is used to confirm and type isolates as A or B. Nearly all positive influenza samples demonstrate detectable virus after 1 week of incubation. NAAT is commonly used for the detection and characterization of influenza viruses. RT-PCR is the current recommended method of detection in most laboratories due to the rapid detection of the virus in clinical specimens with a sensitivity that is equal to or exceeds that of culture-based methods. Several multiplex respiratory panels are also available that include the influenza viruses. Multiplex assays may be less sensitive than a monospecific molecular assay. In addition, several CLIA-waived point-of-care molecular methods are available that can be used in outpatient settings. The molecular point of care assays has demonstrated improved sensitivity over serologic-based rapid antigen tests.

Pediatric Respiratory Viruses

Influenza and parainfluenza viruses, RSV, and adenoviruses should be considered in specimens from hospitalized infants and children younger than 10 years of age with suspected viral lower respiratory tract disease. All viruses can be detected by fluorescent staining of respiratory secretions or rapid cell culture (shell vial). If direct fluorescent staining is used, cell culture confirmation of all negatives should be examined for children suspected of having viruses other than RSV. Many laboratories use R-Mix cells in a rapid shell vial format to detect respiratory viruses (Box 64.1). This approach mixes two cell lines (human lung carcinoma A549 and mink lung fibroblast Mv1Lu cells; Diagnostic Hybrids, Athens, OH) in a single shell vial. Two R-Mix shell vial tubes are inoculated for each specimen. After an 18- to 24-hour incubation, the cell mixture from one tube is stained with a pooled antibody reagent designed to detect all common respiratory viruses. Positive (fluorescent) specimens have the second tube scraped, spotted onto eight-well slides, and stained with individual antibody reagents to identify the specific virus.

If conventional cell culture is used, influenza and parainfluenza viruses are detected in PMK cells by CPEs or hemadsorption. Fluorescent staining is used for confirmation and typing. Adenovirus and RSV are detected in HEp-2 cell culture and confirmed, if necessary, by fluorescent staining. FA staining, conducted by experienced personnel, is equivalent to culture in sensitivity and should be used for single specimens or small batches. Conventional ELISA also is accurate and recommended for large batches of specimens.

Specimens from infants or young children sent for RSV detection should be tested by a rapid, nonculture RSV test. These rapid diagnostic tests (RDTs) come in different formats and may be called dipstick immunoassays, lateral flow immunoassays, or membrane ELISAs. Although these RDTs and related testing methods can be less sensitive than culture, results are available quickly (typically less than 20 minutes) and easily making these methods convenient for testing in an emergency room, urgent care clinic, doctor's office, or pharmacy.

NAAT methods have demonstrated an increased sensitivity and successful diagnosis for RSV over other methodologies. In addition, numerous multiplex molecular systems are also commercially available that include respiratory viral pathogens. These rapid assays have the potential to improve care by decreasing the length of stay and shorten the duration of antimicrobial antibiotic administration.

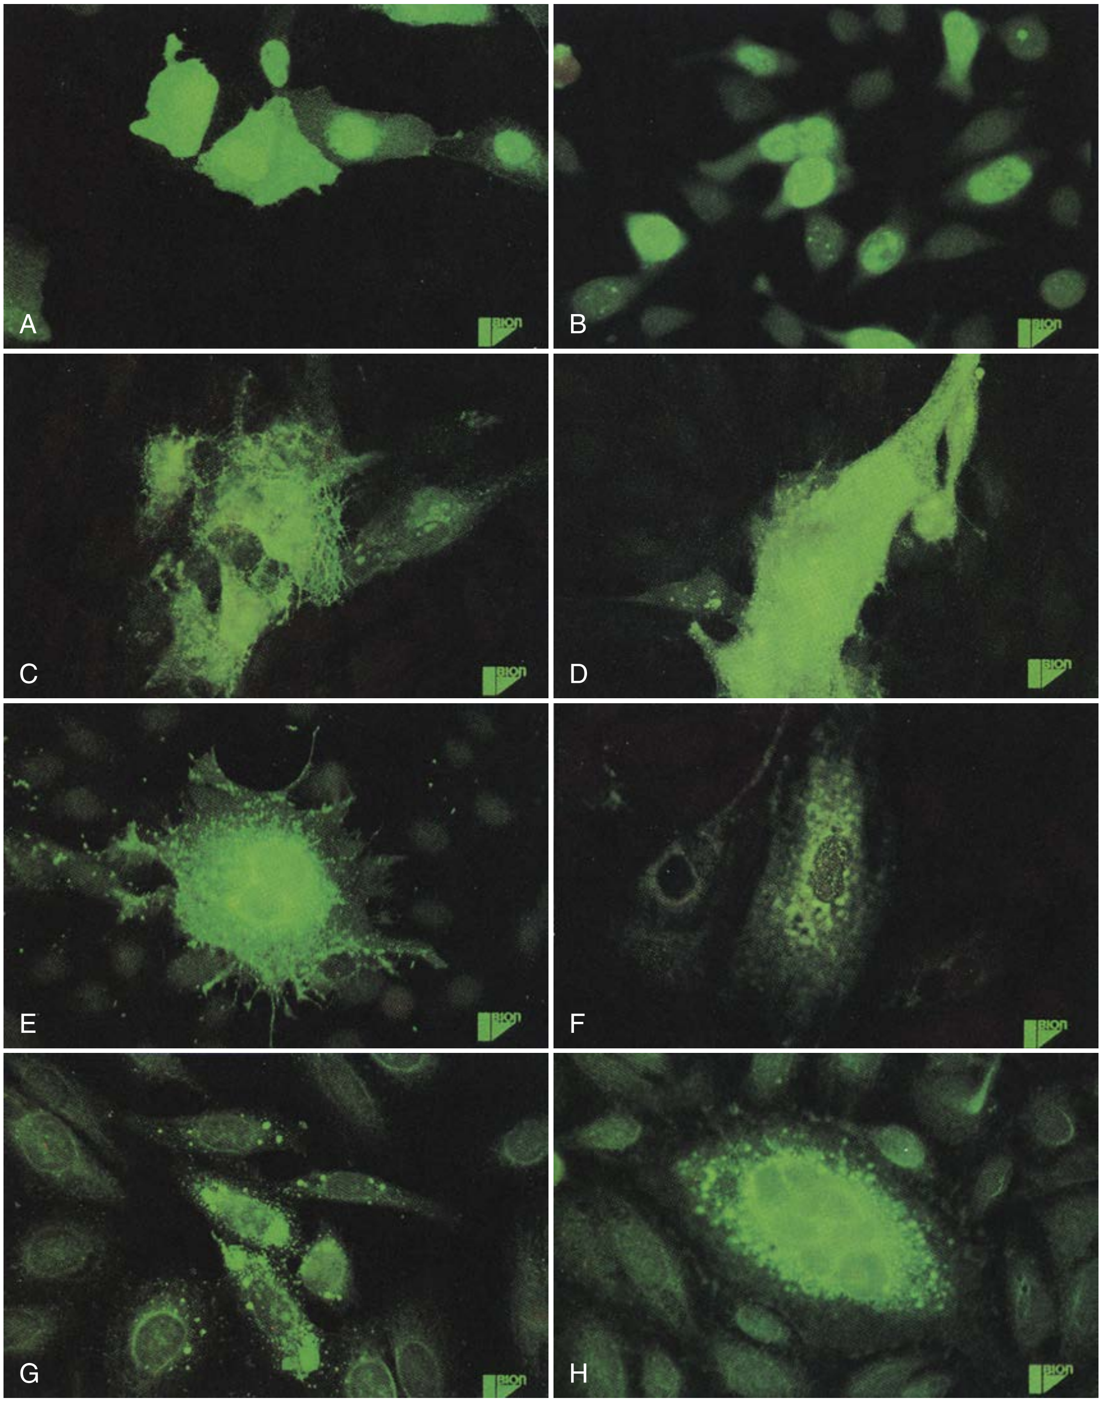
Gastroenteritis Viruses

Immunoassays including microplate EIAs, latex agglutination and rapid membrane-based immunochromatographic assays are commercially available for rotaviruses and enteric adenovirus types 40 and 41. Other viruses, such as astroviruses and caliciviruses that include noroviruses, do not cause life-threatening diarrheal disease; screening is not routinely used for astrovirus. A single norovirus assay, Ridascreen Norovirus 3rd Generation EIA (R-Biopharm AG. Darmstadt, Germany), is FDA licensed for the preliminary identification of norovirus in outbreak situations.

NAAT methods are the method of choice for the rapid detection of gastroenteritis causing viruses. Several monoplex and multiplex assays are commercially available for the detection of gastroenteritis causing viruses including rotavirus, noroviruses, sapovirus, astrovirus, and the enteric adenoviruses.

TORCH

TORCH is an acronym for *Toxoplasma,* rubella, CMV, and HSV. Testing for these agents and for other viral causes of infection in newborns is appropriate during pregnancy. Transplacental infection can result in congenital defects and postnatal complications. CMV is frequently associated with congenital infections.



• **Fig. 64.8** Fluorescent antibody staining of virus-infected cells. (A) Influenza virus. (B) Adenovirus. (C) Varicella-zoster virus. (D) Herpes simplex virus. (E) Respiratory syncytial virus. (F) Parainfluenza virus. (G) Mumps virus. (H) Measles virus. (Courtesy Bion Enterprises, Park Ridge, IL.)

A blanket request for TORCH assays should be avoided when possible, especially in specimens from newborns. Clinical presentation in the newborn may be characteristic for one or two of the viral agents, and tests for these agents should be pursued.

Varicella-Zoster Virus

VZV causes chickenpox (varicella) and shingles (zoster). **Varicella** (a vesicular eruption) is the clinical presentation associated with a primary VZV infection. VZV, a DNA virus, establishes latency in the dorsal nerve root ganglions. Months to years later, during periods of relative immune suppression, VZV reactivates to cause zoster. **Zoster** is a modified or limited form of varicella, localized to a specific **dermatome,** the cutaneous area served by the infected nerve ganglion. Virus is present in the vesicular fluid and in the cells at the base of the vesicle. Material for viral detection should be collected from newly formed vesicles. Once the

• BOX 64.1 Overview of Respiratory Virus Detection by R-Mix Shell Vials

Purpose

To rapidly detect respiratory viruses (influenza A and B viruses; respiratory syncytial viruses; parainfluenza virus types 1, 2, and 3; and adenovirus) using shell vial cell culture and fluorescent antibody staining.

Principle

A shell vial incubated for 24–48 h is stained with a pool of fluorescently conjugated antibodies capable of reacting with common respiratory viruses. If the result is positive, a second shell vial is scraped and applied as multiple spots to a microscope slide for staining with individual antibody conjugates, each specific for a different virus.

Specimen

Lower respiratory tract secretions (sputum, endotracheal or bronchial washes, bronchoalveolar lavages), lung tissue, or nasopharyngeal secretions. Throat swabs and specimens are not recommended.

Materials

- R-Mix shell vials containing a mixture of human lung carcinoma and mink lung cells (Diagnostic Hybrids, Athens, OH)
- Centrifuge
- Incubator
- Fluorescent microscope
- Monoclonal antibody screening reagent pool
- Specific virus monoclonal antibody staining reagents (all conjugated to fluorescein isothiocyanate [FITC])

Methods

1. Thaw, wash, and add refeed medium to cells in shell vials.
2. Inoculate specimen to two duplicate vials.
3. Centrifuge shell vials at 700× g for 1 h.
4. Incubate at 35°C–37°C for 24–48 h.
5. Stain one vial with monoclonal antibody pool screening reagent; if the result is positive, scrape the other shell vial and spot onto an eight-well slide.
6. Stain with specific monoclonal staining reagent to detect the specific virus present.

Interpretation

Report the specific virus detected with specific monoclonal staining reagent. If no fluorescence is detected with the monoclonal pool screening reagent, report as “No Respiratory Viruses Detected.”

Procedure Notes

R-Mix shell vials should be screened and stained at 24 h for influenza A and B viruses. Respiratory syncytial viruses; parainfluenza virus types 1, 2, and 3; and adenovirus require 48 h of incubation for maximum sensitivity.

vesicle has opened and crusted over, detection is unlikely. Virus can be detected by staining cells from the base of the vesicles, by culturing cells and vesicular fluid, or by NAAT testing of fluid and cells.

A stained smear of cells from the base of a skin vesicle used to detect VZV or HSV inclusions is referred to as a Tzanck test (described previously). Giemsa, Papanicolaou (Pap), or another suitable cytologic staining method may be used for the Tzanck test, which detects typical multinucleated giant cells and inclusions (Fig. 64.9A). FA staining also can be used to detect VZV in Tzanck smears. Traditionally, a diploid fibroblast cell culture (e.g., MRC-5) has been used to detect VZV, which requires up to 28 days before visible CPEs is produced. The shell vial assay reduces the detection time to 48 hours and significantly increases sensitivity, identifying virus that fails to produce CPEs in conventional cell culture. Comparison of FA staining of Tzanck smears, conventional cell culture, rapid shell vial culture, and PCR testing shows PCR to be the most sensitive method of detection for VZV. NAAT have improved the diagnosis of VZV disease in the CNS, disseminated infections in immunocompromised patients, and herpes zoster in patients who do not develop the characteristic rash. Qualitative as well as quantitative assays are now available that are highly sensitive and can be performed in many routine diagnostic laboratories. In addition, VZV is included in a variety of multiplex PCR assays, including the BioFire Film Array ME panel.

Virus Detection Methods

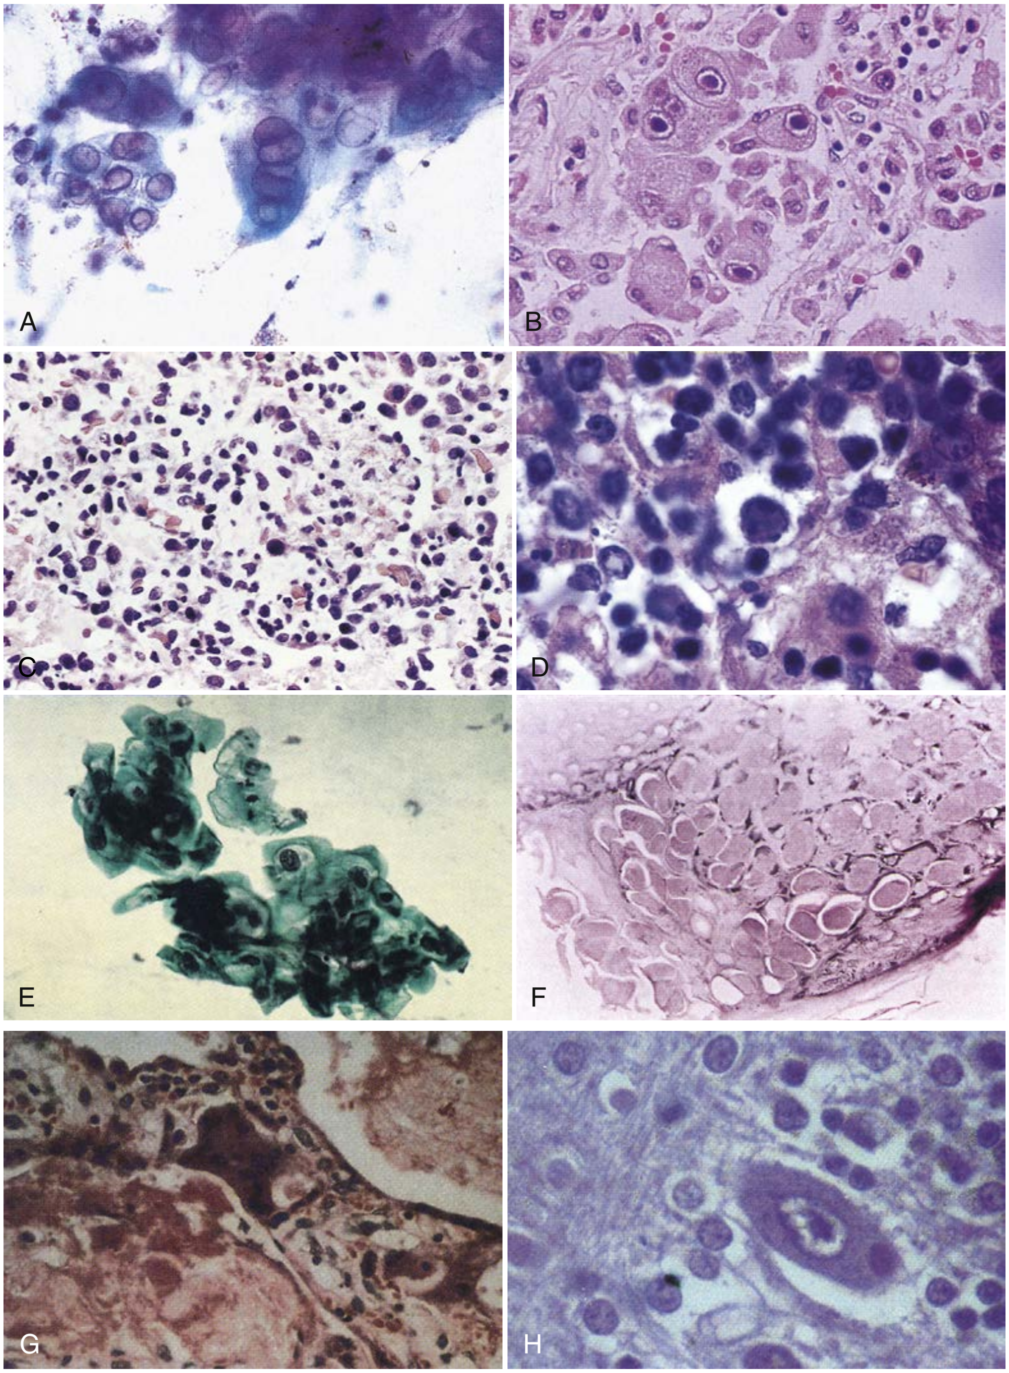
Cytology and Histology

A readily available technique for detecting virus is cytologic or histologic examination for characteristic viral inclusions. This involves the morphologic study of cells or tissue, respectively. **Viral inclusions** are intracellular structures formed by aggregates of virus or viral components in an infected cell or abnormal accumulations of cellular materials resulting from virus-induced metabolic disruption. Inclusions occur in single or syncytial cells. **Syncytial cells** are aggregates of cells fused to form one large cell with multiple nuclei. Pap- or Giemsa-stained cytologic smears may be examined for inclusions or syncytia. Inclusions resulting from infection with CMV, adenovirus, parvovirus, papillomavirus, and molluscum contagiosum virus can be detected by histologic examination of tissue stained with hematoxylin and eosin or Pap (Fig. 64.9B through F). Less commonly, inclusions characteristic of measles and rabies viruses are detected by examining stained tissues (Fig. 64.9G and H). Rabies virus inclusions in brain tissue are called **Negri bodies**. Cytology and histology are less sensitive than culture but were historically used for viruses that are difficult or dangerous to isolate in the laboratory, such as parvovirus and rabies virus, respectively. However, due to the advancement and improvements in the development of NAATs, molecular assays are now available and recommended for the rapid detection of the rabies virus and the B19V parvovirus.

Immunodiagnostics (Antigen Detection)

High-quality, commercially available viral antibody reagents have led to the development of fluorescent antibody, EIA, latex agglutination, and immunoperoxidase tests that detect viral antigen in patient specimens.

Direct and indirect immunofluorescent methods are used. Direct immunofluorescent testing involves the use of



• **Fig. 64.9** Viral inclusions. (A) Papanicolaou-stained smear showing multinucleated giant cells typical of herpes simplex or varicella-zoster viruses. (B) Hematoxylin and eosin (HE)–stained lung tissue containing intranuclear inclusion within enlarged cytomegalovirus–infected cells. (C) HE-stained lung tissue containing epithelial cells with intranuclear inclusions characteristic of adenovirus. (D) HE-stained liver from stillborn fetus showing intranuclear inclusions in erythroblasts (extramedullary hematopoiesis) resulting from parvovirus infection. (E) Papanicolaou stain of exfoliated cervicovaginal epithelial cells showing perinuclear vacuolization and nuclear enlargement characteristic of human papillomavirus infection. (F) HE-stained epidermis filled with molluscum bodies, which are large, eosinophilic, cytoplasmic inclusions resulting from infection with molluscum contagiosum virus. (G) HE-stained cells infected with measles virus. (H) HE-stained brain tissue showing oval, eosinophilic rabies cytoplasmic inclusion (Negri body). (E and F, From Murray PR, Kobayashi GS, Pfaller MA, et al, eds. *Medical Microbiology.* 2nd ed. St Louis: Mosby; 1994.)

a labeled antiviral antibody; the label is usually fluorescein isothiocyanate (FITC), which is layered over a specimen suspected of containing a homologous virus. The indirect immunofluorescent procedure is a two-step test in which unlabeled antiviral antibody is added to the slide, followed by a labeled (FITC) antiglobulin (also called a secondary antibody) that binds to the first-step antibody bound to virus in the specimen. Direct immunofluorescence is generally more rapid and specific than indirect immunofluorescence but less sensitive. The increased sensitivity of indirect immunofluorescence results from signal amplification that occurs with the addition of the second antibody. Signal amplification decreases specificity by increasing nonspecific background fluorescence.

Direct immunofluorescence is best suited to situations in which large quantities of virus are suspected or when high-quality, concentrated monoclonal antibodies are used, such as for the detection of RSV in a specimen or the identification of viruses growing in cell culture.

Indirect immunofluorescence should be used when lower quantities of virus are suspected, such as detection of respiratory viruses in specimens from adult patients. High-quality monoclonal antibodies improve the sensitivity and specificity of immunofluorescence testing.

Strict criteria for the interpretation of fluorescent patterns must be used. This includes standard interpretation of fluorescent intensity (Table 64.6) and recognition of viral inclusion morphology. Nuclear and cytoplasmic staining patterns are typical for influenza virus, adenovirus, and the herpes viruses; cytoplasmic staining is typical for RSV, parainfluenza, and mumps viruses; and staining within multinucleated giant cells is typical of measles virus or the herpes viruses (Figs. 64.9 and 64.10). False-positive staining can occur with specimens containing yeasts, certain bacteria, mucus, or leukocytes. Leukocytes, which contain Fc receptors for antibody, also can cause nonspecific binding of antibody conjugates. To verify the medical laboratorian's ability to interpret FA tests, every laboratory should perform viral culture or some alternative detection method along with immunofluorescence until in-house performance has been established.

The most useful immunofluorescent stains in the clinical virology laboratory are those for RSV, influenza and parainfluenza viruses, adenovirus, HSV, VZV, and CMV. A pool of antibodies can be used to screen a specimen for multiple viruses. A positive screen is tested with each individual reagent to identify the exact virus. Screening pools have been used successfully to detect respiratory viruses in specimens from children. Such pools are less sensitive when used with specimens from adults because of the lower numbers of viral particles typically found in the specimens.

EIA methods used in clinical virology include solid-phase ELISA and the membrane-bound ELISA. Solid-phase ELISA is performed in a small test tube or microtiter tray. Breakaway strips of microtiter wells are available for low-volume test runs. The remaining unused wells can be saved for future testing. Membrane ELISA tests, also known as lateral flow immunoassays or RDTs have been developed for low-volume testing and for cases in which rapid results are needed. They can be performed by individuals with minimal training and usually require less than 20 to 30 minutes to complete. The membrane method uses a handheld reaction chamber with a cellulose-like membrane. The specimen and reagents are applied to the membrane. After a short incubation period, a chromogenic (color) reaction occurs on the surface of the membrane and is read visually. Built-in controls on the same membrane provide convenient monitoring of the test procedure. The most used EIAs for antigen detection are those for RSV (solid-phase and membrane), rotavirus (solid-phase and membrane), and influenza viruses (membrane).

Advantages of EIAs includes the use of relatively stable reagents and results that can be interpreted qualitatively (positive or negative) or quantitatively (titer or degree of positive reaction). It is important to note that EIAs commonly have an indeterminate or borderline interpretative category. This result implies that low levels of viral antigen or background interference prevented a clear-cut positive or negative result. Such results usually require repeat testing of a second specimen to prevent false negative results due to interference with the test method or to detect a rise in antigen level. ELISAs are sensitive and simple to perform and can be easily automated. However, specimen quality cannot be evaluated; that is, the number of cells cannot be assessed, as can be determined microscopically with fluorescent immunoassays.

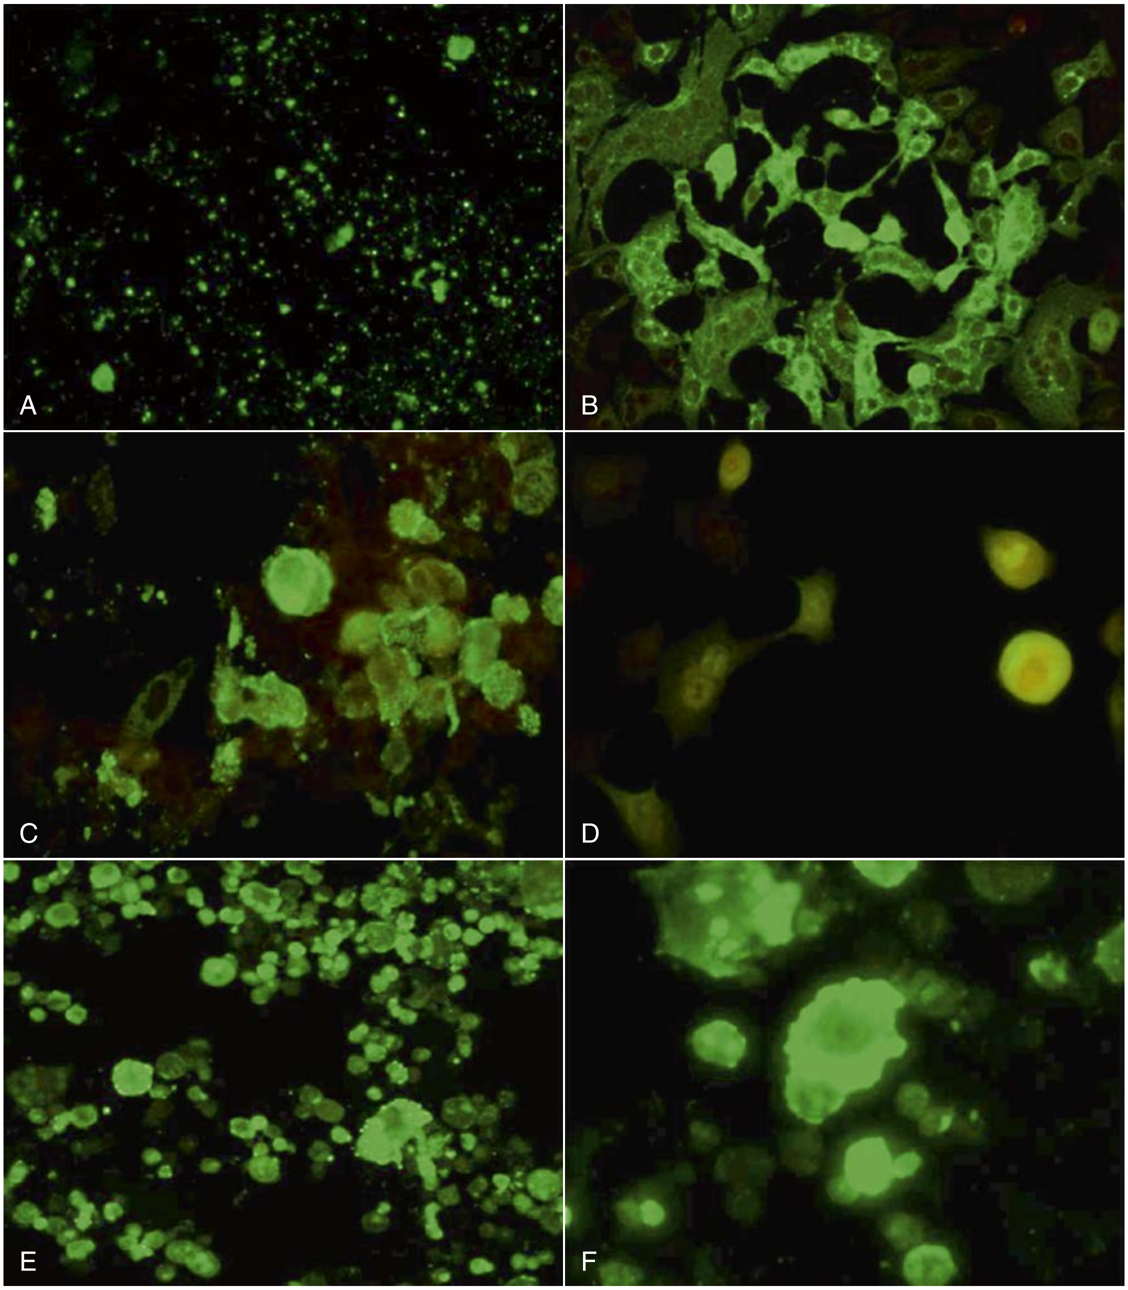
Immunoperoxidase staining and latex agglutination are additional techniques used to detect viral antigens. Immunoperoxidase staining is commonly used to stain histologic sections for virus but is less popular than immunofluorescence staining in clinical virology laboratories. Latex agglutination is an easy and inexpensive method but lacks sensitivity compared with ELISA and fluorescent immunoassays.

Enzyme-Linked Virus-Inducible System

The ELVIS, previously mentioned for HSV detection, uses a baby hamster kidney (BHK) cell culture system with a cloned (added) beta-galactosidase gene that is expressed only when cells are infected with a virus. In the ELVIS-HSV test system (Diagnostic Hybrids, Athens, OH), the genetically engineered BHK cells are attached to the wells of a multiwell microtiter plate. After inoculation of the specimens and overnight incubation, growth of HSV results in the production of the beta-galactosidase enzyme by the BHK cells. Beta-galactosidase serves as the "reporter" molecule. When cells are fixed and stained for beta-galactosidase activity, positive staining indicates the presence of HSV type 1 (HSV-1) or HSV type 2 (HSV-2). Wells that do not contain HSV do not stain.

Nucleic Acid Based Methods

During the past two decades, the introduction of nucleic acid detection techniques into the clinical virology laboratory has resulted in a major shift in testing strategy. With the use of both nucleic acid detection and amplification-based systems, in conjunction with automated nucleic acid isolation techniques for sample preparation, nearly all virology laboratories use commercial or in-house molecular assays, and some laboratories advocate for the complete reliance on molecular detection over viral culture. These technologic improvements make it possible to generate results within 2 to 6 hours because they do not rely upon viral culture techniques. Nucleic acid detection can be accomplished using nucleic acid probes, which are short segments of DNA that hybridize with complementary viral DNA or RNA segments. The probe is labeled with a fluorescent or chromogenic tag that allows detection using nucleic acid hybridization. The probe reaction can occur *in situ,* such as in a paraffin-embedded tissue thin section; in liquid; or in



• **Fig. 64.10** (A) Rhesus monkey kidney (RMK) cells infected with respiratory syncytial virus (RSV) at 400×, stained with Light Diagnostics RSV MoAb. Fluorescence is seen in the cytoplasm and associated with syncytia. Cytoplasmic staining is often punctate with small inclusions. (B) Herpes simplex virus (HSV) I–infected Vero cell control slide at 200× stained with Pathfinder HSV 1 MoAb DFA assay. Fluorescent staining is cytoplasmic. (C) Influenza B–infected RMK cells at 400×. Stained with Light Diagnostics Influenza B MoAb. Fluorescence is nuclear, cytoplasmic, or both. Nuclear staining is uniformly bright, and the cytoplasmic staining is often punctate with large inclusions. (D) HSV II–infected A549 cells at 200× stained with Pathfinder HSV II MoAb DFA assay. Fluorescence may stain the cytoplasm, the nucleus, or both depending on the stage of the infection cycle. When infected cells are rounded, staining may appear nuclear because of the cytoplasm covering the nucleus. (E) HSV II–infected A549 cells at 200×. (F) HSV II–infected A549 cells at 400×. Picture shows the multinucleated “giant” cells characteristic of HSV II cytopathogenic effect (CPE).

a reaction vessel or on a membrane surface. A DNA probe test used to detect papillomavirus DNA in a smear of cervical cells is illustrated in Fig. 64.11. Nucleic acid probes are most useful when the amount of virus is relatively abundant; viral culture is slow or not possible; and the available immunoassays lack sensitivity or specificity.

When there are too few DNA target fragments in the original specimen to be detected by a nucleic acid probe, then the targets can be amplified using molecular techniques such as PCR to increase the nucleic acid copies within a detectable range. These and other molecular techniques are described in more detail in Chapter 8. The PCR reaction with ensuing

amplicon identification has been automated and made very rapid. Quantitative PCR testing, or real-time PCR, is illustrated in Fig. 64.12. In real-time PCR, target amplification and detection occur simultaneously in the same tube; with conventional PCR, amplification and product detection take place separately. The PCR product can be detected as it is produced; novel fluorogenic probes or fluorescent dyes are used to monitor the reaction and detect the PCR product as it accumulates. This requires special thermal cyclers with precision optics that can monitor the fluorescent emission from the sample wells.

The PCR can be used similarly to amplify and detect RNA viruses by using the reverse transcriptase (RT) enzyme. The first step in reverse transcription (RT-PCR) includes making a complementary DNA strand of the RNA segment in question. The usual PCR steps used to multiply the DNA target are then performed, leading to DNA amplicons that, when identified, signify the presence of the original RNA sequence. The rapid appearance and broad application of molecular diagnostics require the introduction and use of standardized materials and external quality control programs. In addition, the use of universal internal controls throughout the procedure ensures accuracy. Several new multiplex assays and microassays capable of detecting multiple viruses in a single reaction have been developed. These assays are particularly useful for the diagnosis of respiratory pathogens and are described in more detail in Chapter 65. Advances in the direct detection of viral particles by NAAT has provided rapid detection of viruses in less than 1 hour. This has resulted in a decreased need for viral culture for the diagnosis and management of viral diseases. In addition, FDA approved quantitative nucleic acid viral load testing in blood is improving. CLIA-waived NAATs have been introduced that include closed system devices with results available in 20 to 30 minutes for infectious agents such as influenza A and B and RSV and 60 minutes for multiple viruses and bacterial pathogens in a single sample in multiplex syndrome panels.

Cell Culture

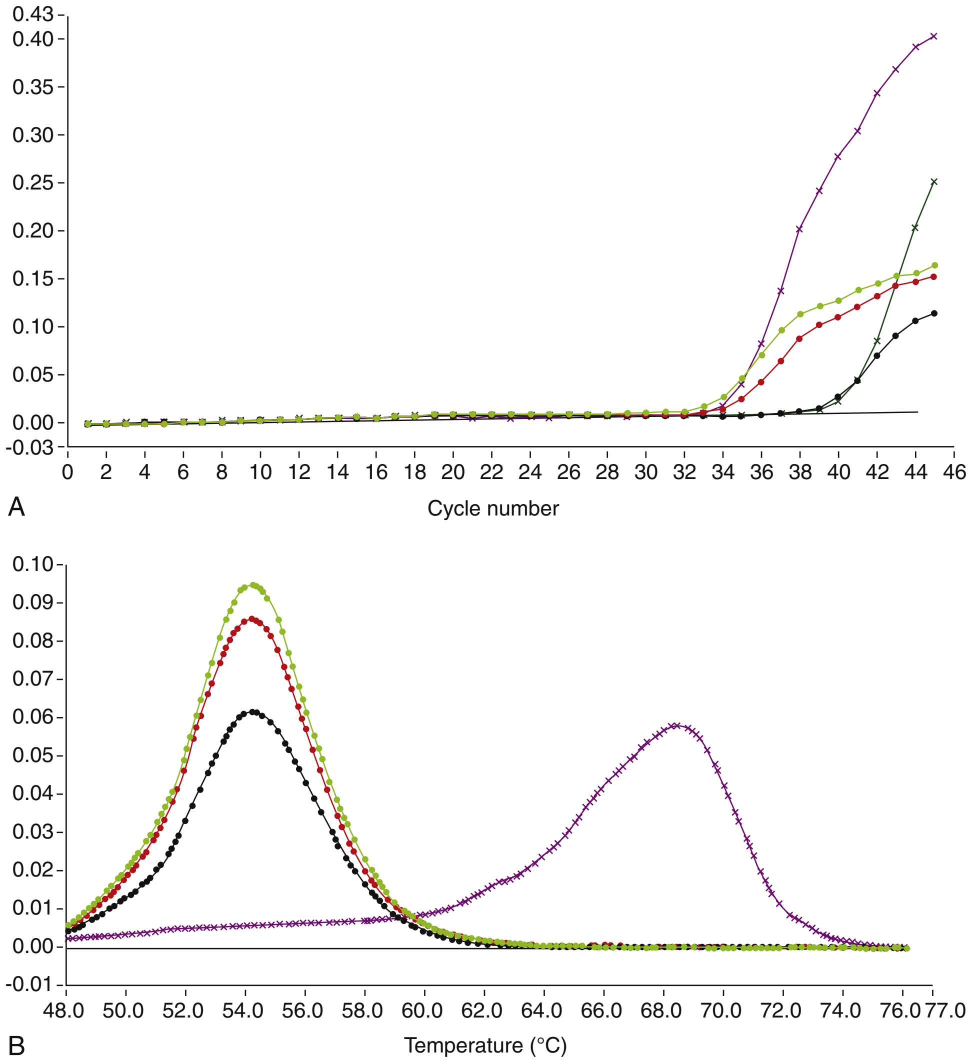
Conventional Cell Culture

Viruses are strict intracellular parasites, requiring a living cell for multiplication and reproduction. To detect virus using living cells, suitable host cells, cell culture media, and techniques in cell culture maintenance are necessary. Host cells, referred to as **cell cultures** (referred to by some as **tissue cultures**), originate as a few cells and grow into a **cell monolayer** (single confluent layer) on the sides of glass or plastic test tubes. The cells are kept moist and are supplied with nutrients by keeping them continuously immersed in a cell culture medium. Cell cultures are routinely incubated in a roller drum that holds cell culture test tubes tilted 5 to 7 degrees while they slowly revolve (0.5 to 1 rpm) at 35°C to 37°C (Fig. 64.5). Cell culture tubes can be incubated in a stationary rack rather than a roller drum. Rapidly growing viruses, such as HSV, appear to be equally detected using either of the two methods. Comparative studies are not available for most viruses.

Metabolism of growing cells in a closed tube results in the production of carbon dioxide and acidification of the growth medium. To counteract the pH decrease, a bicarbonate buffering system is used in the culture medium to keep the cells at physiologic pH (7.2). Phenol red, a pH indicator that remains red at physiologic pH, yellow at acidic pH, and purple at alkaline pH, is added to monitor the pH of the medium. Once inoculated, cell cultures are incubated for 1 to 4 weeks, depending on the suspected viral agents. Periodically the cells are inspected microscopically with an inverted light microscope for the presence of virus, indicated by areas of rounded, dead, or dying cells (the CPE). The degree of CPEs is graded from 1+ to 4+; 1+ involves 25% of the cell monolayer; 2+ involves 50%; 3+ involves 75%; and 4+ involves 100% of the cell monolayer.

Virus-induced CPE also presents two other important considerations: the rate at which CPE progresses and whether the type of cell culture in which the virus grows may be used for presumptive identification. An example of rate can be seen with HSV, in which CPE progresses rapidly to involve the entire cell monolayer. In contrast, two other herpes viruses, VZV and CMV, grow slowly, mainly in human diploid fibroblasts (HDFs), and CPE progresses over several days or weeks. The fact that the cell culture type may serve as an indicator of the presumptive identification can be seen with poliovirus and echovirus. Poliovirus and echovirus produce similar CPE in primary rhesus monkey kidney (RMK) cells, but echovirus does not induce CPE in continuous cell lines, whereas poliovirus does. A trained virologist can determine whether CPE is a result of viral growth or is nonspecific because of cell toxicity from the addition of the specimen, contamination with bacteria or fungi, or simply old culture cells. Inoculation into fresh cells should amplify viral effects and dilute toxic effects.

Two kinds of media, **growth medium** and **maintenance medium,** are used for cell culture. Both are prepared with Eagle's minimum essential medium (EMEM) in Hanks' or Earle's balanced salt solution (HBSS or EBSS, respectively) and include antimicrobials to prevent bacterial contamination. HBSS has a better buffering capacity with carbon dioxide (CO_2), whereas EBSS has a better buffering capacity in ambient air. Added antimicrobials typically include vancomycin



• **Fig. 64.12** Real-time polymerase chain reaction (PCR) detection of herpes simplex virus (HSV). *Black, red,* and *light green lines* represent three different HSV type 1 (HSV-1) viruses. *Pink* and *dark green lines* represent two different HSV type 2 (HSV-2) viruses. (A) Cycle crossover detection of HSV-1 and HSV-2 amplicons, with all viruses detected between cycles 34 and 40. (B) Melt curve confirmation of the presence of HSV-1 and HSV-2 viruses. HSV-1 amplicons melt at approximately 54°C (three HSV-1 viruses confirmed), and HSV-2 amplicons melt at approximately 68°C (one HSV-2 virus confirmed).

(10 µg/mL), gentamicin (20 µg/mL), and amphotericin (2.5 µg/mL). Growth medium is a serum-rich nutrient medium (10% fetal, newborn, or agammaglobulinemic calf serum) designed to support rapid cell growth. This medium is used to initiate the growth of cells when cell cultures are prepared in-house or to feed purchased cell cultures that have incomplete cell monolayers. **"Feeding"** refers to the removal of old medium, followed by the addition of fresh culture medium.

Maintenance medium is similar to growth medium but contains less serum (0% to 2%) and is used to keep cells in a steady state of metabolism. Fetal, newborn, or agammaglobulinemic calf serum is used to avoid inhibitors of virus replication, such as specific antibodies, and because it is free of mycoplasmas present in the serum of older animals.

Several kinds of cell cultures are routinely used for isolation of viruses. A cell culture becomes a **cell line** once it has been passed, or subcultured, *in vitro.* Cell lines are classified as primary, diploid (semicontinuous), or continuous. **Primary cell lines** have been passed only once or twice since harvesting (e.g., PMK cells). Further passage of primary cells, such as after experimental immortalization (e.g., through HPV E6/E7 oncoprotein expression), results in a cell line that will replicate indefinitely but typically has decreased receptivity to viral infection. **Diploid cell lines** remain virus-sensitive through 20 to 50 passages. Human dermal fibroblasts (HDFs), such as lung fibroblasts, are a commonly used diploid cell line. **Continuous cell lines,** such as human epidermoid carcinoma (HEp-2) cells, can be passed and remain sensitive to virus infections indefinitely. Unfortunately, most viruses do not grow well in continuous cell lines. Most clinically significant viruses can be recovered using one cell culture type from each group. A combination commonly used by clinical laboratories is RMK cells, MRC-5 lung fibroblast cells, and HEp-2 cells or A-549 cells (Table 64.5).

TABLE 64.5 **Cell Culture Isolation and Identification of Common Clinically Encountered Viruses**

Virus	PMK	HEp-2	HDF	CPE Description	Rate of Growth (days)	Identification and Comments
Adenovirus	++[a]	+++	++	Rounding and aggregation of infected cells in grapelike clusters	2–10	Confirm by FA test; serotype by cell culture neutralization
Cytomegalovirus (CMV)	–	–	++++	Discrete, small foci of rounded cells	5–28	Distinct CPEs sufficient to identify; confirm by FA test
Enterovirus	++++	+	++	Characteristic refractile angular or tear-shaped CPEs; progresses to involve entire monolayer	2–8	Confirm by FA test; stable at pH 3
Herpes simplex (HSV)	+	++++	++++	Rounded, swollen refractile cells; occasional syncytia, especially with HSV-2; rapidly involves entire monolayer	1–3 (may take up to 7)	Distinct CPEs sufficient to identify; confirm by FA test
Influenza	++++	–	±	Destructive degeneration with swollen, vacuolated cells	2–10	Detect by hemadsorption or hemagglutination with guinea pig RBCs; identify by FA test
Mumps	+++	±	±	CPEs usually absent; syncytia occasionally seen	5–10	Detect by hemadsorption with guinea pig RBCs; confirm by FA test
Parainfluenza	+++	–	–	CPEs usually minimal or absent	4–10	Detect by hemadsorption with guinea pig RBCs; identify by FA test
Respiratory syncytial virus (RSV)	+	+++	+	Syncytia in HEp-2 cells	3–10	Distinct CPEs in HEp-2 cells sufficient for presumptive identification; confirm by FA test
Rhinovirus	++	–	+++	Characteristic refractile rounding of cells; in PMK, CPE is identical to that produced by enteroviruses	4–10	Labile at pH 3; growth optimal at 32°C–33°C
Varicella-zoster virus	–	–	++	Discrete foci of rounded, swollen, refractile cells; slowly involves entire monolayer	5–28	Confirm by FA test

[a] Relative sensitivity of cell cultures for recovering the virus: –, None recovered; ±, rare strains recovered; +, few strains recovered; ++++, ≥80% of strains recovered.
CPEs, Cytopathic effects; *FA,* fluorescent antibody; *HDF,* human diploid fibroblast; *HEp-2*, human epidermoid; *PMK,* primary monkey kidney; *RBCs,* red blood cells.

Inoculated cell cultures should be incubated immediately at 35°C. After allowing virus to adsorb to the cell monolayer for 12 to 24 hours, the remaining inoculum and culture medium commonly are removed and replaced with fresh maintenance medium. This prevents most inoculum-induced cell culture toxicity and improves virus recovery. Incubation should be continued for 5 to 28 days, depending on the suspected agent (Table 64.5). Maintenance medium should be changed periodically (usually once or twice weekly) to provide fresh nutrients to the cells.

Blind passage refers to passing cells and fluid to a second cell culture tube. Blind passage is used to detect viruses that may not produce CPE in the initial culture tube but produce CPE when the “beefed-up” inoculum is passed to a second tube. Cell cultures that show nonspecific or ambiguous CPE are also passed to additional cell culture tubes. Toxicity, which causes ambiguous CPE, is diluted during passage and should not appear in the second cell culture tube. In both cases, passage is performed by scraping the monolayer off the sides of the tube with a pipette or disrupting the monolayer by vortexing with sterile glass beads added to the culture tube, followed by inoculation of 0.25 mL of the resulting suspension into a new cell culture. Blind passage is less commonly used, because the added time and expense do not justify detection of a few additional isolates after extended incubation in two cell culture tubes.

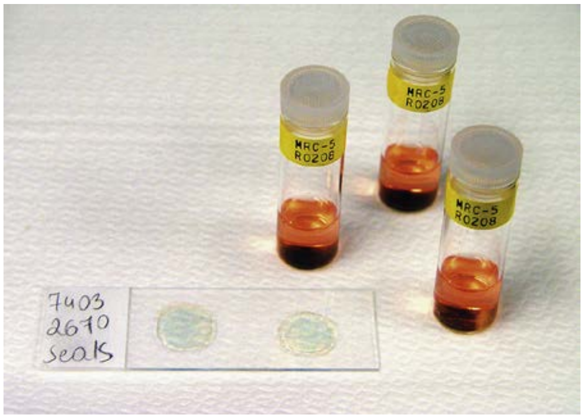
Shell Vial Cell Culture

The **shell vial** cell culture is a rapid modification of conventional cell culture. Virus is detected more quickly using the shell vial technique, because the infected cell monolayer is stained for viral antigens produced soon after infection and before the development of CPEs. Viruses that normally take days to weeks to produce CPEs can be identified within 1 to 2 days by detecting early produced viral antigens. A shell vial culture tube, a 15 mm × 45 mm 1-dram vial, is prepared by adding a round coverslip to the bottom of the tube, covering with growth medium, and adding appropriate cells (Fig. 64.13). During incubation, a cell monolayer forms on top of the coverslip. Shell vials should be used 5 to 9 days after the cells have been added. Shell vials can be purchased with the monolayer already formed. Specimens are inoculated onto the shell vial cell monolayer by low-speed centrifugation. This enhances viral infectivity for reasons that are not well understood. Coverslips are stained using virus-specific immunofluorescent conjugates. The presence and visualization of characteristic fluorescing inclusions are used to confirm the presence of an infecting virus (Fig. 64.14). The shell vial procedure for detecting CMV is presented in detail in Evolve Procedure 64.3.

The shell vial culture technique can be used to detect most viruses that grow in conventional cell culture. It is best used for viruses requiring relatively long incubation before producing CPEs, such as CMV and VZV. The advantage of the shell vial procedure over traditional cell culture is speed; most viruses are detected within 24 hours. The disadvantage is that only a single type of virus can be detected per shell vial. For example, a specimen that might contain influenza A or B or adenovirus would need to be inoculated to three separate shell vials so that each vial could be stained with a separate virus-specific conjugate. Other strategies pool antibody for detection of many viruses with a single vial. Additional vials from positive specimens are then stained with individual conjugates to identify the specific virus present. The shell vial procedure with mixed cell types used to detect seven different respiratory viruses is outlined in Box 64.1.

Identification of Viruses Detected in Cell Culture

Viruses are most often detected in cell culture by the recognition of CPEs. Virus-infected cells change their usual morphology and eventually lyse or detach from the glass surface while dying. Viruses have distinct CPEs, just as colonies of bacteria on agar plates have unique morphologies (Fig. 64.15). CPEs may be quantitated as indicated in Table 64.6. Preliminary identification of a virus frequently can be made based on the cell line that supports viral replication, how quickly the virus produced CPE, and a description of the CPEs (Table 64.5). Experienced virologists can presumptively identify most viruses isolated in clinical laboratories based on these criteria. When confirmation or definitive identification is



• **Fig. 64.13** Shell vial cell culture tubes and stained coverslips. At the bottom of each shell vial tube under the culture medium is a round coverslip with a cell monolayer on the top surface. After incubation, the coverslip is removed, stained, and placed on a microscope slide for fluorescence viewing. Note that two stained coverslips are on the glass slide.

TABLE 64.6 **Quantitation of Cell Culture Cytopathic Effects**

Quantitation	Interpretation
Negative	Uninfected monolayer
Equivocal (±)	Atypical alteration of monolayer involving few cells
1+	1%–25% of monolayer exhibits cytopathic effects (CPEs)
2+	25%–50% of monolayer exhibits CPEs
3+	50%–75% of monolayer exhibits CPEs
4+	76%–100% of monolayer exhibits CPEs

required, additional testing can be performed. Some viruses that produce little or no CPE (e.g., influenza, parainfluenza, and mumps viruses) can be detected by hemadsorption, because infected cells contain viral hemadsorbing glycoproteins in their outer membranes. The addition of guinea pig red blood cells (RBCs) to the cell culture tube, followed by a wash to remove nonadsorbed RBCs, results in a ring of RBCs around infected cells (Fig. 64.15G). Cell cultures demonstrating hemadsorption can be stained with fluorescent-labeled antisera to identify the specific hemadsorbing virus present. Detailed procedures for culture confirmation by FA staining and hemadsorption for the detection of influenza and parainfluenza viruses are presented in Evolve Procedures 64.4 and 64.5.

Matrix-Assisted Desorption Ionization Time-of-Flight Mass Spectrometry

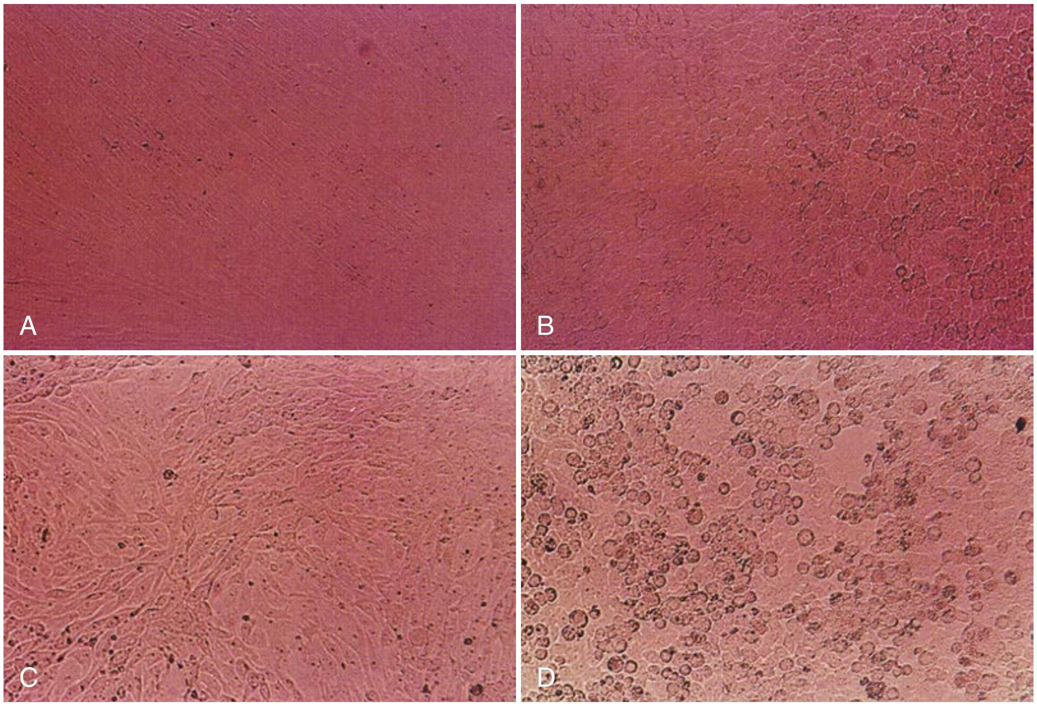
While already a mainstay in clinical laboratories for identification of microbial and fungal pathogens, **mass spectrometry** has also emerged as an important tool for viral detection when combined with PCR amplification or viral culture. MS is an analytical technique that precisely measures the mass of proteins or DNA fragments in a sample. Benefits of MS include rapid, accurate, and specific analysis of proteins, oligonucleotides, and carbohydrates. When used following PCR, MS analysis provides precise measurement of the amplicon mass generated during the PCR reaction. This exact mass measurement allows determination of the base composition of the amplified DNA and deconvolution of that information into potential sequences based on comparison against well-constructed databases of logical possibilities. Furthermore, the use of multiple broad-range and specific PCR primers supports detection of unknown viral species, evaluation of strain relatedness, and identification of resistance genes from a single specimen making this a very powerful diagnostic technique. When used following culture (limited to cultivable viruses), MS analysis of the viral proteome (nucleocapsid, glycoproteins, etc.) can be used in pathogen identification as well as improving scientific understanding of viral infection and pathogenesis. Limitations of MS for viral diagnostics include the heavy reliance upon known reference databases for comparison of spectral signatures to establish a positive identification of one or more pathogens present in a sample. In addition, the presence of unwanted proteins or biological materials can impede MS analysis.

There are a variety of commercially available matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) systems on the market today that exist as standalone fully- or semi-automated instruments. Manufacturers include Agilent, bioMérieux, Bruker, Sciex, Shimadzu, Thermo Fisher Scientific, and Waters, just to name a few. Again, an important barrier in adopting MS in clinical settings has been demonstrating to the FDA that tests have been validated in real-world clinical settings. However, the enormous potential of MALDI-TOF MS to provide rapid, nontargeted bacterial and viral detection continues to drive development and adoption of this technology in clinical laboratories.

Serologic Testing

General Principles

Viral serologic methods are used primarily to determine a patient's immune status and to confirm the patient's



• **Fig. 64.15** Cell culture morphology and viral cytopathic effects. (A) Normal human diploid lung fibroblast cells (HDF). (B) Normal HEp-2 cells. (C) Normal primary monkey kidney cells (PMK). (D) HEp-2 cells infected with adenovirus.

(From US Department of Health, Education, and Welfare, Public Health Service, Centers for Disease Control, Atlanta, GA.)

diagnosis when the virus cannot be cultivated in cell culture or detected readily by immunoassay or molecular methods.

In most viral infections, IgM is undetectable 1 to 4 months after the acute infection resolves, but detectable levels of IgG remain for the life of the patient. If a patient is infected with an antigenically similar virus or the original strain has remained latent and reactivates later, virus-specific IgG and IgM antibody levels may increase. The secondary IgM response may be difficult to detect; however, a significant IgG rise in titer (fourfold) is typically apparent in immunocompetent patients.

An immune status check measures whether a virus has previously infected a patient. A positive result with a sensitive, virus-specific IgG test indicates past infection. Some immune status tests include methods that can detect both IgG and IgM; these are used to identify recent or active infections.

To diagnose active disease, two approaches are helpful. Detection of virus-specific IgM in an acute-phase specimen collected at least 7 to 14 days after the onset of symptoms indicates current or very recent disease. Detection of a fourfold (or equivalent increase if twofold dilutions are not tested) antibody titer rise between acute and convalescent sera also indicates current or recent disease. Acute-phase serum should be collected as soon as possible after the onset of symptoms. The convalescent specimen should be collected 2 to 3 weeks after the acute-phase specimen. If a single post-acute serum, collected between acute and convalescent times, or a convalescent specimen is all that is available for testing, an extremely high, virus-specific IgG titer may suggest infection. The exact titer specific for active disease, if known at all, varies with each testing method and virus. In general, titers high enough to be diagnostic are unusual, and single specimens should not be tested. A reasonable policy would involve using IgM tests, where available, and performing IgG tests only on paired acute and convalescent specimens. IgG tests are not needed on the first, acute specimen until receipt of the convalescent specimen. This eliminates useless testing of single specimens when a second sample is never submitted for analysis.

Many serologic methods are or have been routinely used to detect antiviral antibody. Prominent among these are ELISA, indirect immunofluorescence, anticomplement immunofluorescence (ACIF), and Western immunoblotting. An advantage of ELISA is that it can be used to detect IgM-specific antibodies free of common interfering factors, particularly through use of an antibody-capture technique. Indirect immunofluorescence is best used for individual specimens or small-batch testing.

Immunofluorescence also can be used to detect virus-specific IgM; however, it requires prior separation and elimination of the IgG fraction, which if present can result in both false-positive and false-negative results. IgM and IgG can be separated by ion exchange chromatography; by immune precipitation; or with an IgG inactivation reagent, such as Gullsorb (Meridian Bioscience), a reagent containing an antihuman IgG reagent (caprine) capable of neutralizing up to 15 mg/mL of IgG antibody in human serum.

IgG indirect FA testing is subject to false-positive results because of antibody-Fc receptors that occur in cells infected with virus. Indirect immunofluorescence antibody (IFA) testing is performed using virus-infected substrate cells fixed to a microscope slide. When the substrate cells are overlaid with patient serum, the Fc portion of the antibody molecule binds to these receptors. Fluorescent-labeled antiglobulin attaches to both homologous antibody (bound to viral antigen) and to Fc-bound antibody. Subsequent fluorescence of Fc-bound antibody results in a false-positive or falsely elevated reading. To prevent this complication, the ACIF test can be used. Because fluorescent-labeled complement binds only to antigen-antibody complexes, the nonspecific antibody attached by Fc receptors, which is complement free, does not fluoresce. Western immunoblotting is also used for viral antibody detection. Because complex antigens are separated into individual components during the Western blot procedure, and positive or negative reactions are observed with each of these components, the Western blot provides a more specific result than other serologic tests, such as EIA.

False-positive and false-negative results can occur when testing for virus-specific IgM antibodies. False-positive results occur when rheumatoid factor, an anti-IgG/IgM-type globulin, combines with homologous or virus-specific IgG present in the patient specimen. Labeled anti-IgM combines with either bound virus-specific IgM or rheumatoid factor, causing falsely positive fluorescence. False-negative IgM test results occur when high levels of strongly binding homologous IgG antibodies prevent binding of IgM molecules, decreasing or eliminating IgM-specific fluorescence. Both problems can be eliminated by testing the IgG-free serum fraction.

Immune Status Testing

Immune status tests are used to determine if patients have been infected with (or vaccinated for) a virus in the past, conferring lifelong immunity to reinfection. Rubella antibody immune status testing is used for women of childbearing age. A positive result (presence of IgG antibody) indicates past infection or immunization and implies that congenital infection will not occur during subsequent pregnancies. Absence of IgG antibody implies susceptibility to infection and should prompt rubella vaccination if the woman is not pregnant. Varicella and measles assays are used most commonly for assessing the immune status in health care workers. Those with no IgG antibody must avoid infected patients and receive a booster or secondary vaccination. CMV immune status is useful for organ transplant donors and recipients and premature babies hospitalized in newborn intensive care nurseries who are likely to receive blood transfusions. Transplant recipients are also susceptible to life-threatening CMV infection. Knowing the CMV status of the donor and recipient enables the physician to monitor the transplant patient and when necessary to treat the patient. Newborns whose mothers were never infected with CMV are susceptible to serious, primary CMV infection that can be transmitted in white blood cells (WBCs) during blood transfusion. CMV-negative babies should receive only CMV-negative blood.

Serology Panels

In some cases, testing for antibody to an individual virus is less helpful than using a battery of antigens to test for antibody to many viruses. The use of a combination of serologic tests to diagnose a clinical syndrome may be useful when the viruses under consideration cannot be cultured;

specimens of infected tissue are not available (e.g., brain tissue); antiviral agents have been administered; or the patient is convalescing and isolation of virus is unlikely. In most cases, some but not all viruses in a panel may require testing. Consultation with the patient's physician can narrow the list of potential viral agents that may be the cause of the infection.

Preservation and Storage of Viruses

Clinical virology laboratories must have a method for storing and retrieving viruses, along with an accurate inventory system from which to identify and locate stored viruses. Isolates should be kept as control strains and, in rare instances, for epidemiologic investigations or clinical research applications. Public health laboratories may use current EV or influenza virus strains for typing. Viruses can be stored by freezing at −70°C or in liquid nitrogen. Freezing at −70°C is more practical for clinical laboratories. A method for preserving and storing viruses by freezing is described in Evolve Procedure 64.6.

Visit the Evolve site for a complete list of procedures, review questions, and case studies.

CASE STUDY 64.1

A previously healthy, 19-year-old college student presents to the emergency department (ED) with symptoms of a respiratory tract infection. While in the ED, the patient experiences severe shortness of breath. He is transferred to the intensive care unit and is intubated and placed on a ventilator. A chest radiograph reveals left lung infiltrates.

Questions

1. What viruses cause serious respiratory tract disease in young adults?
2. What specimens are recommended to aid the diagnosis of viral respiratory tract infection?
3. What viral diagnostic tests are appropriate for detecting respiratory tract viruses?

PROCEDURE 64.1

Processing Blood for Viral Culture: Leukocyte Separation Using Polymorphprep

Purpose

Detection of most viruses in blood specimens is facilitated by the separation and culturing of leukocytes. An exception is enterovirus, which may be found free in serum in infected newborns. Leukocytes originally were added to cell culture by harvesting the buffy coat after concentration by centrifugation (100× g, 15 min). This method was found to be inferior to white blood cell concentration using density gradient centrifugation and sedimentation with Ficoll-Paque/Macrodex. Other density gradient methods have been used, including those using Plasmagel, LeucoPREP, Sepracell-MN, Mono-Poly Resolving Medium, and Polymorphprep. Leukocyte preparation using Polymorphprep, a mixture of sodium metrizoate and dextran, has emerged as one of the best, because mononuclear and polymorphonuclear cells are separated from red blood cells in a one-step procedure.

Specimen

Three to 5 mL of anticoagulated blood is optimal. Tubes containing ethylenediaminetetraacetic acid (EDTA), citrate, or heparin anticoagulant can be used. As little as 2 mL of specimen is acceptable for pediatric patients. Clotted specimens are unacceptable. Specimens should be processed immediately. When a processing delay is unavoidable, the specimen should be held at 2°C–8°C. Processing must occur within 12–24 h. Loss of virus may occur during any processing delay.

Materials

1. Polymorphprep (Axis-Shield PoC AS; Oslo, Norway [U.S. supplier is Fischer Scientific]). Store at or below 20°C.
2. Phosphate-buffered saline (PBS) 10×. Store at room temperature.
3. Sterile phosphate-buffered saline 0.5×. Dilute 10× PBS 1:20 with distilled water. Filter-sterilize through 0.22-µm filter. Store at 2°C–8°C.
4. Eagle's minimal essential medium (EMEM) + 2% fetal bovine serum (FBS). Store at 2°C–8°C.
5. Sterile sodium chloride (0.9%). Store at 2°C–8°C.
6. Sterile conical centrifuge tubes.
7. Sterile pipettes.
8. Centrifuge.

Method

1. Wear latex gloves and a laboratory coat when handling patient specimens. Use a biologic safety cabinet (BSC) whenever the specimen tube is opened. Use biocontainment safety covers during centrifugation procedures.
2. Allow the blood specimen and all reagents to come to room temperature.
3. Mix the blood specimen well by inverting five times. Using a 5- or 10-mL pipette, transfer the specimen to a sterile conical centrifuge tube.
4. Centrifuge at 500 × g for 10 min at room temperature (18°C–22°C).
5. Remove plasma with a pipette.
6. Measure the approximate volume of the remaining cells. Using a 5- or 10-mL pipette, dilute cells with the same approximate volume of 0.9% sodium chloride. Mix well.
7. Add 3.5 mL of Polymorphprep to a 15-mL conical centrifuge tube with a 5-mL pipette.
8. Carefully layer the entire volume of diluted blood cells over the 3.5 mL of Polymorphprep in the centrifuge tube. Do not mix the blood with the Polymorphprep.
9. Centrifuge the tube containing blood and Polymorphprep at 450× to 500× g for 30 min at room temperature (18°C–22°C).
10. Two leukocyte bands should be visible after centrifugation. The top band at the blood sample–Polymorphprep interface consists of mononuclear cells. The lower band contains polymorphonuclear cells. Erythrocytes are pelleted at the bottom of the tube.
11. Using a Pasteur pipette, collect the mononuclear and polymorphonuclear bands and transfer them to a 15-mL conical centrifuge tube.
12. Add 5 mL of 0.5× sterile PBS to the centrifuge tube containing the harvested cells. Mix well by aspirating and expelling repeatedly with a pipette.
13. Centrifuge cells at 400× g for 10 min at room temperature (18°C–22°C).
14. Aspirate supernatant PBS.
15. Add 5 mL of EMEM with 2% FBS to pelleted cells. Mix well by aspirating and expelling repeatedly with a pipette.
16. Centrifuge as in step 13.
17. Aspirate supernatant EMEM and resuspend in 2 mL of fresh EMEM with 2% FBS.
18. The specimen is ready for inoculation to cell culture.

Troubleshooting

1. If all cells are at the top of the Polymorphprep after centrifugation, remix and overlay on top of a new Polymorphprep layer. The volume of Polymorphprep may need to be increased so that the proportion is still approximately 1:1 to 1:1.5. Centrifuge at either increased force of gravity for the same length of time or at the same force of gravity for a longer time.
2. If the buffy coat is on top of the erythrocyte layer, take the buffy coat and erythrocytes and layer over a new gradient. Centrifuge for a shorter time at the same force of gravity or at a lesser force of gravity for the same time.

PROCEDURE 64.2

Cytomegalovirus Antigenemia Stain

Purpose

The cytomegalovirus (CMV) antigenemia stain is used for immunologic detection of cytomegalovirus lower matrix pp65 antigen in peripheral blood leukocytes. The assay is semiquantitative in that white blood cells are counted, and a standard number are placed on the slide for staining. Experience with the CMV antigenemia stain suggests that positive results can serve as an early indicator of active CMV disease.

Specimen

A total of 5–7 mL of anticoagulated blood is optimal. Tubes containing heparin or ethylenediaminetetraacetic acid (EDTA) anticoagulant can be used. Specimens should be transported to the laboratory at room temperature immediately after collection. Clotted specimens are unacceptable. Specimens should be processed immediately. When processing delay is unavoidable, hold specimen at 2°C–8°C. Processing should occur within 8 h.

Materials

1. CMV Brite Kit (Biotest Diagnostic, Denville, NJ), which includes dextran solution, red blood cell (RBC)–lysing solution, fixative solution, permeabilization solution, fetal calf serum, monoclonal antibodies, and control slides. Store at 2°C–8°C.
2. Sterile pipettes and micropipettes.
3. Refrigerated centrifuge and 15-mL conical bottom centrifuge tubes.
4. Cytocentrifuge (Shandon, Pittsburgh, PA).
5. Phosphate-buffered saline (PBS), calcium- and magnesium-free deionized water (dH_2O).
6. Coplin staining jars, moisture chamber, 37°C incubator, microscope slides for cytospin, coverslips, and mounting medium.
7. Coulter counter for white blood cell (WBC) count (hematology laboratory).
8. Fluorescent microscope.

Method

1. Wear latex gloves and a laboratory coat when handling patient specimens. Use a biologic safety cabinet (BSC) whenever a tube containing a specimen is open. Use biocontainment safety covers during centrifugation procedures.
2. Isolate leukocytes from peripheral blood:
   a. Allow kit reagents to come to room temperature (20°C–25°C).
   b. Mix 5–7 mL of anticoagulated blood with 1.5 mL of dextran reagent (reagent A) in a 15-mL conical centrifuge tube. If a greater volume of blood is used, the dextran-to-blood ratio of 1:4 must be maintained.
   c. Incubate the tube containing the blood-dextran mixture for 20 min at 37°C at a 45-degree angle. Leave the cap loose.
   d. Remove the top, leukocyte-rich layer to a 15-mL conical centrifuge tube using a Pasteur pipette. Centrifuge for 10 min at 300× g.
   e. Dilute RBC lysing reagent (reagent B) 1:10 in dH_2O and allow to cool to 4°C.
   f. Discard supernatant after 10-min centrifugation. Resuspend cell pellet in 5 mL of diluted reagent B. Vortex and incubate for 5 min at 4°C.
   g. Add 5 mL of PBS and centrifuge for 10 min at 300× g.
   h. Wash cells in 5 mL PBS, centrifuge as previously, and discard supernatant.
3. Count cells and prepare cell dilution:
   a. Suspend cell pellet in 1.5 mL PBS.
   b. Aliquot 0.4 mL into a 1.5-mL microcentrifuge tube. This aliquot is used for a leukocyte count.
   c. Dilute cell suspension with PBS to make 1 mL of 2×10^6 cell/mL in a 1.5-mL microcentrifuge tube. Calculate the amount of cell suspension to use as follows:

$$\text{Desired number of } \frac{\text{cells}}{\text{mL}} \div \text{Actual number of cells}$$
$$= \text{Amount of suspension required}$$

For example:

$$2 \times 10^6 \text{ cells/mL} \div 5 \times 10^6 \text{ cell/mL} =$$
$$2 \div 5 = 0.4 \text{ mL cell suspension}$$

Add enough PBS to increase the volume to 1 mL.

For example: If the amount of cell suspension needed is 0.4 mL, add 0.6 mL of PBS to make 1 mL.

4. Perform cytospin preparation of slides:
   a. Prepare two cytospin slides for testing.
   b. Resuspend 1 mL cell suspension by vortexing the tube.
   c. Add 100 μL of the cell suspension in the cytospin assembly.
   d. Centrifuge at 800 rpm for 4 min.
   e. Remove the slides and air dry.
5. Perform fixation and permeabilization:
   a. Dilute the fixation reagent (reagent C) 1:5 in dH_2O in a fume hood (5 mL reagent C, 20 mL dH_2O).
   b. Flood slides with diluted reagent C and incubate at room temperature in a fume hood for 10 min.
   c. Prepare 100 mL of 1% washing solution by diluting reagent E 1:100 in PBS (1 mL reagent E, 99 mL PBS). Fill 1 Coplin jar with 1% washing solution.
   d. Dip slides three times in 1% washing solution and place slides in same Coplin jar for 5 minutes.
   e. Dilute permeabilization solution (reagent D) 1:5 in dH_2O (5 mL reagent D, 20 mL dH_2O).
   f. Immerse slides in dilute permeabilization solution for 5 minutes.
   g. Fill Coplin jar with fresh 1% wash solution. Dip slides three times in 1% wash solution and place slides in same Coplin jar for 5 min.
   h. Rinse slides in dH_2O for 15 s, then let slides dry. When dry, slides are ready for immediate staining. If the slides are not to be stained immediately, store at 2°C–8°C for 24 h or up to 24 h at −20°C. Wrap slides in foil and store in a desiccated environment for extended storage.
6. Perform immunofluorescent staining:
   a. Allow the slides, including the control slide, to come to room temperature. Mark a small circle around the cell area (cytospin area) on the slide to contain the antibody solution during staining.
   b. Immerse the slides in the Coplin jar containing PBS for 5 min. Once the slides have been immersed, do not allow the specimen area to dry through the remainder of the staining procedure.
   c. Working with one slide at a time, remove a slide from the Coplin jar and carefully dry the area around the

PROCEDURE—CONT'D

specimen with a sterile cotton swab. Place the slide in a moisture chamber and apply 35 μL of monoclonal antibody (reagent F).
   d. Incubate the slides for 30 min at 37°C.
   e. Remove the slides from the staining chambers and rinse in a Coplin jar with fresh PBS for 3 min.
   f. Again, working with one slide at a time, remove the slide from the Coplin jar and dry the area around the specimen with a sterile cotton swab. Place the slide in a moisture chamber and apply 35 μL of fluorescein isothiocyanate (FITC)–conjugated antibody to the slide.
   g. Incubate the slides for 30 min at 37°C.
   h. Wash the slides in PBS and rinse with dH_2O. Drain excess water and air dry. Do not blot.
   i. Add mounting medium and coverslip.
7. Read and report results:
   a. Examine the slides using a fluorescent microscope and ×200 magnification (×10 eyepiece, ×20 objective).
   b. Read soon after staining (same day) because the intensity of the fluorescence fades. Scan the whole cell spot on both slides.
   c. Positive cells show a homogeneous, apple-green nuclear staining, as demonstrated in the positive control. Negative cells show no apple-green staining. Nonspecific staining, which appears as cytoplasmic or dull yellowish staining, should be reported as negative. Atypical greenish staining of cells on the periphery of the cell inoculum is a result of drying artifact and should be reported as negative.
   d 200,000 cells should be present on each slide, 400,000 per two slides.
      (1) Report positive stains as "Positive: (number) CMV positive cells seen per 400,000 cells."
      (2) Report negative stains as "No CMV positive cells seen per 400,000 cells analyzed."

Quality Control

1. The negative control should have no CMV-infected cells showing fluorescence.
2. The positive control should have CMV-infected cells showing homogeneous, apple-green nuclear staining.
3. If the controls do not appear as described in 1 and 2, the results are unacceptable, and the test must be repeated.

PROCEDURE 64.3

Shell Vial Culture for Cytomegalovirus

Purpose

The shell vial culture for cytomegalovirus (CMV) is used to rapidly detect the virus in clinical specimens. Use of the shell vial culture with urine, blood, and bronchoalveolar lavage fluid specimens has demonstrated equivalent or superior sensitivity to that achieved with conventional cell culture.

Specimen

Acceptable specimens include urine, blood, respiratory secretions and washes, tissue, and cerebrospinal fluid. Specimens are collected, transported, and stored according to standard protocols.

Materials

1. Shell vials, 15 × 45 mm, 1-dram vial with plastic closure
2. Circular coverslips, No. 1 12-mm diameter
3. MRC-5 cells growing in shell vial (5–9 days old)
4. In place of steps 1–3, MRC-5 shell vials purchased from commercial source (e.g., BioWhittaker, Walkersville, MD, or ViroMed Laboratories, Minneapolis, MN)
5. Centrifuge; sterile 15-mL conical centrifuge tubes
6. Sterile 1- and 5-mL pipettes and cotton-plugged sterile Pasteur pipettes
7. pH paper (3–9 pH)
8. Maintenance medium
9. CMV positive control (strain AD 169)
10. Negative control (use maintenance medium with no virus)
11. Anti-CMV early nuclear protein monoclonal antibody
12. Fluorescein isothiocyanate (FITC)–labeled antimouse IgG conjugate
13. Phosphate-buffered saline (PBS)
14. Methanol, forceps, buffered glycerol mounting medium, and glass microscope slides

Methods

1. Wear latex gloves and a laboratory coat when handling patient specimens. Use a biologic safety cabinet (BSC) whenever a tube containing a specimen is open. Use biocontainment safety covers during centrifugation procedures.
2. Specimen preparation
   a. Urine
      (1) Using a 5-mL pipette, transfer 2 mL of urine into a sterile centrifuge tube.
      (2) Using a 1-mL pipette, add 0.5 mL of viral transport medium containing antimicrobials.
      (3) Centrifuge at 1000× g for 10 min at 2°C–8°C.
      (4) Aspirate supernatant with cotton-plugged sterile Pasteur pipette and transfer to a sterile test tube.
      (5) Adjust pH to 7.0 with sterile cold 0.1 N hydrogen chloride (HCl) or 0.1 N sodium hydroxide (NaOH). Determine pH with pH paper.
      (6) Store at 2°C–8°C until inoculation into shell vial cultures.
   b. Blood: Refer to leukocyte separation by Polymorphprep (Evolve Procedure 64.1). Store leukocytes at 2°C–8°C until inoculation into shell vial cultures.
   c. Respiratory secretions and washes
      (1) Process as for urine; pH adjustment is not necessary.
      (2) Specimens received in viral transport medium do not require further preparation.
      (3) Store all specimens at 2°C–8°C until inoculation into shell vial culture.
   d. Tissue
      (1) Mince three pieces of tissue (each approximately 5 mm in size) gently in approximately 5 mL of viral transport medium. This results in a 10% suspension.
      (2) Centrifuge at 1000× g for 10 min at 2°C–8°C.

Continued

PROCEDURE—CONT'D

- (3) Aspirate supernatant with cotton-plugged sterile Pasteur pipette and transfer to small sterile test tube.
- (4) Store at 2°C–8°C until inoculation into shell vial culture.

e. Cerebrospinal fluid (CSF)
  - (1) CSF and other body fluids are inoculated into a shell vial culture undiluted.
  - (2) Specimens with less than sufficient volume for proper inoculation (≤0.5 mL) should be diluted with enough viral transport media to inoculate shell vial cultures (0.5–0.6 mL).
  - (3) Specimens received in viral transport medium are ready to inoculate.
  - (4) Store at 2°C–8°C until inoculation into shell vial culture.

3. Inoculate and incubate the shell vial cultures
   - a. Aspirate maintenance medium from sufficient shell vials for all specimens, including one positive and one negative control.
   - b. Using a new sterile 1-mL pipette for each specimen, inoculate the shell vials as follows:

Specimen	No. Vials	Inoculum/Vial
Urine	1	0.25 mL
Respiratory	1	0.1 mL
Blood	3	0.25 mL each
All other specimens	2	0.1 and 0.25 mL
Negative control	1	0.1 mL
Positive control	1	0.1 mL

The number of vials and volume of inoculum may vary from laboratory to laboratory, depending on local experience. Inoculate all specimens before inoculating controls. A negative control and a positive control should be included with each batch of shell vial cultures. Inoculate the negative control before the positive control.

   - c. Cap the vials with sterile plastic lids and label them.
   - d. Centrifuge the vials at 700× g for 40 min at 35°C.
   - e. Using a 5-mL pipette, add 2 mL of maintenance medium to each shell vial.
   - f. Recap the vials and incubate at 36°C ± 1°C for 16–24 h.

4. Stain the shell vial coverslips:
   - a. Wear latex gloves and perform the test in a laminar flow hood.
   - b. Remove the lids from the shell vials and aspirate media.
   - c. Wash the coverslips with 1 mL of PBS. Aspirate. Wash again with 1 mL PBS and let stand for 5 min. Aspirate. Additional PBS washes may be necessary for blood cultures, to remove blood cells from cell sheet. If necessary, check cell monolayer using the microscope.
   - d. Fix coverslips in 1 mL of cold methanol for 10 min.
   - e. Aspirate methanol. The coverslips should be allowed to dry but not over dry. A white clearing across the coverslips is apparent at the right amount of dryness. Over drying causes nonspecific fluorescence around the edge. Under drying causes uneven staining.
   - f. Add 150 μL of monoclonal antibody, at current working dilution, to each vial by dropping antibody into the middle of the coverslip. Replace the lids on the shell vials and gently rotate to spread the stain over the entire coverslip. Incubate at 35°C–37°C for 30 min.
   - g. After staining, add 1 mL PBS to each vial (do not remove antibody first). Mix. Aspirate the entire volume of fluid from the vial.
   - h. Wash twice with 1 mL PBS. Let the second wash remain on the coverslip for 5 min. Aspirate PBS; do not allow the coverslips to dry.
   - i. Add 150 μL of anti-immunoglobulin conjugate (FITC), at current working dilution, to each vial by dropping antibody onto the middle of the coverslip. Spread as described in step f. Incubate at 35°C–37°C for 30 min.
   - j. Repeat wash steps g and h. Wash the coverslips an additional time with 1 mL distilled/deionized water for 2 min. A brief rinse may be sufficient for monoclonal antibody conjugates. The more thorough washing is needed for polyclonal reagents.
   - k. Using small forceps, remove the coverslips from the vials and place cell side down on a drop of mounting medium. Wipe the tips of the forceps with alcohol-soaked gauze between each coverslip.
5. Read and interpret the shell vial coverslips: Read the entire coverslip using the ×20 fluorescence microscope objective. The nuclei of CMV-infected cells exhibit an apple-green fluorescence that may vary in intensity (Fig. 64.15). Infected nuclei may be distinguished from artifacts by their regular oval shape and evenly stained, slightly granular appearance. Occasionally the nuclei may appear rounded. The background should stain a dull red or a pale green (dull red if Evan's blue counterstain is used with conjugate; pale green if no counterstain is used).

Quality Control

1. The negative control coverslip should have no fluorescing nuclei typical of a CMV-infected cell.
2. The positive control coverslip should have multiple fluorescing nuclei typical of CMV-infected cells.

PROCEDURE 64.4

Culture Confirmation by Fluorescent Antibody Staining

Purpose

Many viruses can be identified presumptively in cell culture by observing cytopathic effects (CPEs). Definitive identification (or in some cases typing) of a virus in cell culture can be accomplished by staining a smear of infected cells with a virus-specific antibody conjugate. Results are easier to interpret if CPEs of at least 2+ are noted before cells are collected for staining.

Materials

1. Virus-specific antibody conjugate
2. Phosphate-buffered saline (PBS)
3. Glass slides with circled staining areas and coverslips
4. 25-µL pipettes and tips
5. Control slides with homologous virus for positive staining and nonhomologous virus for negative staining
6. Mounting fluid (25% buffered glycerol in PBS)
7. Sterile glass beads
8. Centrifuge
9. Pasteur pipettes

Specimen

1. Cells can be collected from the surface of the glass test tube by scraping with a 1-mL pipette, adding 3–4 sterile glass beads and disrupting by vortexing, or detaching cells with trypsin. Scraping is best if the CPEs are less than 2+. Areas of CPEs can be circled on the outside of the culture tube with a marker. If only these areas are scraped on the inside, the relative number of virus-infected cells will be greater, and detection will be easier in the stained smear. Although trypsin treatment is the traditional method for releasing cells, the use of glass beads during vortexing is simple and reliable. The glass bead method is described.
    a. Add 3 or 4 sterile glass beads to the cell culture tube. Vortex vigorously for 15–30 s. Examine microscopically to ensure that the cells are detached from the glass. Vortex a second time if cells remain on the glass.
    b. Pellet cells by centrifugation at 900× g for 10 min. Carefully remove supernatant.
    c. Wash cells by resuspending the pellet in PBS and repeat centrifugation.
    d. Remove supernatant and resuspend in 0.05–0.1 mL of PBS.
    e. Place a 25-µL aliquot of the cell suspension onto two wells on clean, labeled slides. Prepare enough smears to test with antisera for all viruses under consideration.
    f. Air dry at temperatures no higher than 30°C and fix in acetone for 10 min. Slides may be stored at –70°C.
2. Determine the working dilution of the fluorescent conjugate if not supplied by the manufacturer.
    a. Prepare serial doubling dilutions of the stock conjugate in PBS.
    b. Test each conjugate dilution for its ability to stain smears of homologous and nonhomologous virus-infected cells, in addition to smears of normal uninfected cells.
    c. The working dilution of the antiserum is the highest dilution producing 3+ to 4+ fluorescence of homologous virus, 1+ or less fluorescence of nonhomologous virus, and no fluorescence of uninfected cells.

Method

1. Apply the working dilution of the conjugate to the circled areas on the slide. Cover the entire circled area (approximately 25 µL of conjugate per circle).
2. Place the slides in a moist chamber and cover the chamber to minimize evaporation. Incubate the slides at 35°C for 20 min. Be careful not to tilt the slides, because the conjugates will run together.
3. Do not allow the conjugate to dry on the slide, because this results in nonspecific staining.
4. Tip the slides to drain conjugate from the smear. Remove excess reagent with running PBS, followed by a 5-min PBS wash in a Coplin jar. Agitate the slide occasionally during the wash. A brief rinse with no agitation may be sufficient for monoclonal antibody conjugates. The more thorough washing is needed for polyclonal reagents.
5. Rinse the slides in distilled water to remove PBS salt crystals.
6. Allow the slides to air dry at room temperature. Protect them from bright light.
7. Apply mounting fluid and a coverslip.
8. Examine the slides with a fluorescence microscope containing appropriate filters for fluorescein isothiocyanate (FITC) staining (490 nm UV needed). Use 20× and 40× objectives.

Interpretation of Results

1. Positive staining cells are characterized by at least 1+ apple-green fluorescent intranuclear and/or cytoplasmic granules.
2. Negative staining cells are characterized by no or less than 1+ fluorescence. Uninfected cells may stain red if Evan's blue counterstain is used.

Quality Control

1. Positive and negative controls should be used each time the stain is performed.
2. The positive control (homologous virus) should exhibit at least 2+ staining.
3. The negative control (nonhomologous virus) should exhibit less than 1+ staining.
4. If control results are different from those expected, the stain should be repeated.

PROCEDURE 64.5

Hemadsorption of Primary Monkey Kidney Monolayers to Detect Influenza, Parainfluenza, and Mumps Viruses

Purpose

Hemadsorption of cell cultures is used to detect or confirm the presence of orthomyxoviruses (influenza A, B, and C) and some paramyxoviruses (parainfluenza 1–4 and mumps). Respiratory syncytial virus is not detected by this method. Cell cultures infected with these viruses may not show cytopathic effects (CPEs); however, infected cells do acquire the ability to hemadsorb guinea pig red blood cells (RBCs) to their outer cell membranes. In addition, the presence of viral hemagglutinin in the culture medium, after release from the cell, can also cause agglutination of the RBCs in the fluid medium.

Hemadsorption is performed on various days during culture incubation, depending on the time of year and the viruses suspected. Influenza virus detection is performed on specimens from adult and pediatric patients during the influenza season (November to March). Early hemadsorption (day 2 or 3) decreases time to detection of positive influenza cultures. Detection of parainfluenza viruses from pediatric patient specimens is performed year-round. Hemadsorption produced by parainfluenza viruses generally occurs later than that produced by influenza. In most clinical settings, hemadsorption to detect mumps virus is performed if the virus is suspected.

Specimen

1. A culture exhibiting CPEs should be hemadsorbed as soon as possible to expedite reporting of a positive result.
2. Perform hemadsorption on CPE-negative cell cultures of respiratory tract specimens or of specimens for mumps virus detection according to the following schedule:

Culture Type	Days to Perform Hemadsorption
Influenza virus suspected	2 and 7
Parainfluenza virus suspected	3 and 10
Mumps virus suspected	3 and 10

Materials

1. Guinea pig RBCs. Store in buffer in which cells were received at 2°C–8°C. Cells expire 10 days after date drawn from animal.
2. Sterile, 10× phosphate-buffered saline (PBS). Prepare working 1× PBS by diluting with distilled water. Filter (0.22 μm) sterilize. Store at 2°C–8°C.
3. Viral culture maintenance medium with antibiotics.
4. Positive control virus (parainfluenza virus) in tube of current lot of primary monkey kidney (PMK) cells.
5. Negative control is uninoculated tube of current lot of PMK cells.
6. Sterile, conical centrifuge tubes.
7. Sterile pipettes.
8. Repeater Eppendorf pipettes.
9. Centrifuge.

Method

1. Prepare the guinea pig RBCs:
    a. Transfer the guinea pig cells to a 15-mL conical centrifuge tube. Centrifuge for 5 min at 500× g (2°C –8°C). Aspirate supernatant and buffy coat.
    b. Resuspend the RBCs in cold (2°C–8°C) PBS. Wash in cold PBS until the supernatant is clear (2 or 3 times).
    c. Aspirate PBS after last wash. Measure remaining volume of cells using graduations on the centrifuge tube. Add a sufficient amount of PBS to make a 10% cell solution.
    d. The hemadsorption test is performed using a 0.4% guinea pig cell solution prepared with maintenance medium. Depending on the number of tubes to be tested (0.2 mL/tube), prepare as follows: 0.2 mL 10% RBCs + 4.8 mL medium (25 tubes) or 0.4 mL 10% RBCs + 9.6 mL medium (50 tubes).
2. Perform hemadsorption test:
    a. Wear latex gloves and a laboratory coat during the procedure. Perform the test in a biologic safety cabinet (BSC).
    b. Aspirate maintenance medium from all patient and control tubes to be tested.
    c. Add 0.2 mL of the 0.4% RBC suspension to each tube. Be careful not to cross-contaminate the tubes. Positive and negative controls should be tested last.
    d. Gently tilt the stationary rack from side to side to ensure RBC contact with the cell monolayer. Place the stationary rack in the refrigerator (2°C–8°C) for 30 min. The tubes should be placed horizontally so that the erythrocyte suspension covers the monolayer.
    e. After incubation, invert the tubes quickly to dislodge RBCs lying on the cell sheet. Examine the cell culture tubes microscopically with 4× objective for RBCs that adhere to the monolayer. Culture fluids should be inspected for hemagglutination.

Interpretation

1. Negative: No hemadsorption of guinea pig cells and no hemagglutination of cells in the fluid medium. RBCs float freely in the medium. Positive: Hemadsorption of guinea pig cells to infected PMK cells or hemagglutination of RBCs in the fluid medium. Hemadsorption is graded on a scale of 1+ to 4+ as follows:
    1 + =<25% of cell sheet showing hemadsorption
    2 + = 25%–50% of cell sheet showing hemadsorption
    3 + = 51%–75% of cell sheet showing hemadsorption
    4 + = 76%–100% of cell sheet showing hemadsorption
2. Viruses that both hemadsorb and hemagglutinate guinea pig erythrocytes are usually influenza virus. Mumps and parainfluenza viruses generally produce only hemadsorption. Identification of a virus causing hemadsorption should be confirmed using virus-specific antibody conjugates. Certain simian viruses that may contaminate the PMK cells hemadsorb at 4°C (see Quality Control). Examine all tubes as soon as possible after removal from the refrigerator because the neuraminidase of the myxoviruses is active at room temperature and destroys hemagglutinins if the tubes are left for extended periods at this temperature.

Quality Control

1. Positive control: Parainfluenza virus should exhibit at least 2+ hemadsorption.
2. Negative control: Uninoculated PMK cells should exhibit no hemadsorption. If hemadsorption attributed to an endogenous simian virus occurs, the patient specimen must exhibit more hemadsorption than the negative control to be considered positive.

PROCEDURE 64.6

Preservation and Storage of Viruses by Freezing

Purpose

Viral isolates should be saved for use as quality control strains or for epidemiologic investigation. Maximal recovery of virus is accomplished when cells and fluid are collected from infected culture tubes.

Materials

1. Sterile glass beads
2. Dimethyl sulfoxide (DMSO)
3. Dry ice and acetone
4. Freezer tubes

Method

1. In all steps, open cell culture tubes in a biologic safety cabinet (BSC). For viruses other than cytomegalovirus (CMV) and varicella-zoster virus (VZV):
   a. Select tubes showing at least 2+ cytopathic effects (CPEs) or hemadsorption. Red blood cells (RBCs) may be eluted after hemadsorption by placing tubes in a 37°C water bath for 15 min. Wash to remove RBCs.
   b. Add three sterile glass beads to the cell culture tube. Tighten the cap. Vortex vigorously behind a shield for 30 s. Examine the tube microscopically to ensure that cells have been disrupted and removed from the glass surface.
   c. Add the cells and medium to a freezer tube. Snap-freeze the samples by swirling the tube in a slurry of dry ice and acetone.
   d. Store at –70°C.
2. CMV and VZV: Use tubes showing at least 3+ CPEs. Harvest as described previously, except add 10% DMSO and glass beads. For example, add 0.2 mL of DMSO to 2 mL of medium in cell culture tube. Mix and proceed as described previously.
3. Thaw in a 37°C water bath. Inoculate to appropriate cell culture.

Chapter Review

1. In the clinical virology laboratory, *most* manipulation of viruses occurs at what safety level?
- **a.** BSL 1
- **b.** BSL 2
- **c.** BSL 3
- **d.** No biosafety is needed; manipulations are done on the bench.

2. What pH indicator is added to the cell culture growth medium to monitor pH changes?
- **a.** EMEM
- **b.** Fetal bovine serum
- **c.** EBSS
- **d.** Phenol red

3. Unlike with other herpes viruses, asymptomatic shedding does not occur with this virus, and therefore detection is always significant:
- **a.** HSV 1
- **b.** HSV 2
- **c.** VZV
- **d.** CMV

4. An example of a virus that exhibits latency is:
- **a.** Adenovirus
- **b.** RSV
- **c.** Measles
- **d.** HSV

5. Respiratory specimens are best collected with what type of swabs?
- **a.** Calcium alginate swabs
- **b.** Dacron- or polyester-tipped swabs
- **c.** Swabs with cotton tips or wooden shafts
- **d.** All of the above are acceptable

6. The best laboratory test for detecting astrovirus is:
- **a.** EIA
- **b.** IFA
- **c.** RT-PCR
- **d.** EM

7. R-mix shell vials are best used to detect what virus?
- **a.** EV
- **b.** Norovirus
- **c.** Respiratory viruses (e.g., influenza, RSV)
- **d.** Rhinovirus

8. The macromolecular synthesis in the virus infectious cycle:
- **a.** Is the process by which structural proteins, genomes, and sometimes enzymes are assembled into virions
- **b.** Includes the production of nucleic acid and protein polymers
- **c.** Releases the viral genome before the viral nucleic acid is delivered to its intracellular site of replication
- **d.** All of the above

9. CMV is best detected in which type of specimen?
- **a.** Blood or urine
- **b.** Nasal swab
- **c.** Throat or nasopharyngeal swab
- **d.** Vesicle fluid or scraping

10. Sin nombre virus is best detected in which type of specimen?
- **a.** Nasal swab
- **b.** Stool
- **c.** Serum for antibody testing
- **d.** Brain biopsy

11. Rhinovirus is best detected in which type of specimen?
- **a.** Throat or nasopharyngeal swab
- **b.** Nasal swab
- **c.** Bronchial lavage
- **d.** CSF

12. Which instrument is used to detect CPEs in cell culture?
- **a.** Fluorescent microscope
- **b.** Electron microscope
- **c.** BSC
- **d.** Inverted light microscope

13. An example of the cells used for primary cell culture type is:
- **a.** RMK cells
- **b.** Lung fibroblast cells
- **c.** HeLa cells
- **d.** Human epidermoid carcinoma cells

14. Which of the following is not part of the viral infectious cycle?
- **a.** Attachment to a suitable host cell
- **b.** Environmental exposure
- **c.** Assembly of the structural proteins and genome
- **d.** Release or shedding of intact virus

15. Which piece of equipment would not likely be found in a clinical virology lab?
- **a.** BSC
- **b.** Incubator with roller bottles
- **c.** Refrigerator/freezers
- **d.** Vending machine for snacks

16. A non-enveloped or "naked" virus would likely exhibit which of the following characteristics?
- **a.** High susceptibility to drying and destruction in the environment
- **b.** Resistance to environmental factors
- **c.** Oncolytic functions in endothelial cells
- **d.** Fast viral infectious cycle

17. Mass spectrometry can be used to detect which of the following?
- **a.** Viruses
- **b.** Bacteria
- **c.** Fungi
- **d.** All of the above
- **e.** None of the above

18. True or False

_____ Release of the virions from the host cell by budding results in rapid host cell death.

_____ Icosahedral capsids are cubical and have 20 flat sides, whereas helical capsids are spiral-shaped.

_____ The function of the glycoprotein spikes extending from the capsid of the virus is to act as a defense mechanism against the host immune system.

_____ A mechanism of viral penetration involves fusion of the viral envelope with the host cell membrane.

_____ An example of an oncogenic virus is the measles virus.

_____ Cell culture is the best laboratory method for detecting rotavirus.

_____ Specimens for viral culture should be frozen in viral transport media and transported to the laboratory frozen at −20°C.

_____ Viruses are best detected in blood specimens by separating the WBCs from the RBCs and then inoculating a cell culture with the RBCs.

_____ The CMV antigenemia stain is used for immunologic detection of the CMV lower matrix pp65 antigen in peripheral blood leukocytes.

_____ VZV CPE detection in conventional cell culture can take up to 28 days, whereas the shell vial assay can reduce the detection time to 48 hours.

_____ Rapid diagnostic tests have no place in the clinical virology laboratory.

_____ Mass spectrometry, molecular techniques, and increasing automation are trends that will likely continue in the modern clinical laboratory.

19. Matching: *Match each term with the correct description.*

_____ cytopathogenic effect
_____ cell lysis
_____ nucleocapsid
_____ naked virus
_____ blind passage
_____ oncogenic virus
_____ cell budding
_____ autoimmune pathogenesis
_____ viremia
_____ syncytia
_____ obligate intracellular parasite
_____ virion
_____ capsid
_____ antigenemia
_____ capsomere

a. passing of cells and fluid to a second cell culture tube to help detect CPEs
b. cell death
c. require a "host" cell for replication
d. multinucleated mass of cells
e. entire virus or virus particle
f. release of virus from cell with minimal cell destruction
g. ability to stimulate uncontrolled growth of host cells
h. virus circulating in the blood
i. protein coat of the virus
j. virus genome and capsid
k. individual subunits that make up the capsid
l. immune response that cross reacts with related human tissue, resulting in damage to host function
m. virus without a glycoprotein envelope
n. Viral proteins in the blood
o. presence of virus indicated by areas of dead or dying cells in cell culture

20. **Short Answer**

(1) Define viral latency and name the family of viruses in which this often occurs.
(2) Define viral trophism.
(3) Where does primary viral infection most often occur in the human body? What happens after this initial localized infection?
(4) Explain the laboratory procedure for hemadsorption and name the viruses it is best used to detect.
(5) Explain some of the causes of false-positive results in immunofluorescent staining.
(6) Describe how proper specimen transport and storage can positively/negatively impact molecular analysis.
(7) Vaccines are a safe and reliable method to prevent viral diseases. Describe the individual and population-level benefits of immunization.

65

Viruses in Human Disease

OBJECTIVES

1. List the common human respiratory viruses and modes of transmission.
2. Differentiate between viral antigenic shift and antigenic drift. Explain how each occurs, its effect on the production of vaccine, and why it is an important consideration in the study of the influenza virus.
3. Define the term *pandemic* and identify pandemics of the past century, including the latest influenza and SARS-CoV-2 pandemic.
4. List the serotypes of rhinovirus and explain how testing for rhinovirus is accomplished and how it differs from testing for the other respiratory viruses.
5. Define arbovirus, describe the mode of transmission, and list some of the most common human arboviruses.
6. List the viruses responsible for viral encephalitis.
7. Name the most common sexually transmitted viral diseases.
8. Define tissue tropism associated with human papillomavirus (HPV) and explain the relationship between HPV and cervical cancer.
9. Define skin exanthema and identify the most common types that affect children.
10. Compare human gastrointestinal viruses, stating the types that affect adults more frequently and those that affect children.
11. Define hanta pulmonary syndrome; identify the disease-causing virus and the mode of transmission.
12. Describe the term *zoonotic* and list at least three zoonotic viruses.
13. Name the family of viruses responsible for the skin eruptions orf and molluscum contagiosum.
14. List the family of viruses responsible for outbreaks of severe disease among military recruits and describe the recommended preventive measures.
15. Define the viral proteins hemagglutinin and neuraminidase; explain how these proteins function to ensure the transmissibility and reproducibility of the influenza virus.
16. Explain the benefits and limitations associated with nucleic acid–based testing methods for the detection and monitoring of disease progress in viral syndromes or infection.
17. Correlate the agents of specific infections discussed in this chapter with diseases and pathologic manifestations, including routes of transmission and appropriate diagnostic tests.
18. Describe the molecular basis of prion diseases and list those most commonly identified.

Viruses in Human Disease

Viruses of medical importance to humans comprise 10 families of deoxyribonucleic acid (DNA) viruses and 21 families of ribonucleic acid (RNA) viruses. This chapter examines the specific families of viruses, including the diseases and the symptoms associated with the viral infection. Tables 65.1 and 65.2 divide the virus families according to the makeup of the viral genome, either RNA or DNA, and are a quick reference for the viruses.

Adenoviridae

Adenoviruses are large (70 to 90 nm), icosahedral, nonenveloped, single double-stranded, linear DNA viruses. This virus was first isolated from cultures of human adenoids and tonsils in the early 1950s, hence the name **adenovirus.**

TABLE 65.1 Major Families of Medically Important Deoxyribonucleic Acid Viruses

Virus Families (in Order of Increasing Size)	Size (nm)	Envelope	Capsid Symmetry	Genome Structure	Viruses
Parvoviridae	~22	No	Icosahedral	SS	Parvovirus B19 virus Human bocaviruses Human bufavirus Parv4
Papillomaviridae	~55	No	Icosahedral	DS Circular	Human papillomaviruses
Polyomaviridae	40–45	No	Icosahedral	DS Circular	John Cunningham (JC) and BK (renal transplant patient initials) polyomaviruses Merkel cell polyomavirus Trichodysplasia spinulosa polyomavirus
Hepadnaviridae	42	Yes	Pleomorphic	DS Incomplete circular	Hepatitis B virus
Adenoviridae	70–90	No	Icosahedral	DS	Human adenoviruses (85 serotypes)
Herpesviridae	120–300	Yes	Icosahedral	DS	Herpes simplex viruses type 1, 2 Varicella-zoster Cytomegalovirus Epstein-Barr Human herpesvirus (HHV-6, HHV-7, and HHV-8 (KSHV)
Poxviridae	200–450	Yes	Oval or brick-shaped	DS	Variola Vaccinia Orf Molluscum contagiosum Monkey-pox viruses

DS, Double-stranded; *KSHV,* Kaposi sarcoma-associated virus; *SS*, single-stranded.

The adenoviruses belong to the family *Adenoviridae* and are widely distributed in nature. However, only members of the genus *Mastadenovirus,* referred to as adenoviruses, cause human infection. Currently, 85 serotypes of human adenoviruses have been described. Based on molecular methods, types 52 to 85 are defined as genotypes. Genotypes can be more closely associated with types of virulence and clinical symptoms. Differentiation of serotype and genotype is not necessary unless there is a specific property that is clinically significant such as an observable difference in the immunological response based on virulence of the virus. In addition, within genotypes, molecular variants have been identified as subtypes or genome types and are designated with lowercase letters after the numbered type. These types are then divided into seven species, A through G, with species B subdivided into two subspecies (B1 and B2); virus types are then numbered within the species classification. The viruses can cause a broad range of disease in humans. Respiratory and gastrointestinal diseases are the most common clinical manifestation associated with adenovirus infection.

Adenoviruses cause less than 5% of all acute respiratory disease in the general population; however, they account for up to 15% of all acute diarrheal infections in children. By the age of 10 years, most children have been exposed to and infected with at least one of the adenovirus species. In addition, adenovirus F-type 40 and 41 cause gastroenteritis in infants and young children, and other types are associated with conjunctivitis and keratitis. Small outbreaks of gastroenteritis associated with adenovirus A, types 12, 18, 31, and 16, have also been reported. Although respiratory and gastrointestinal diseases are most common, disseminated disease in multiple organ systems may develop in compromised hosts. Infections are frequent and severe in pediatric hematopoietic stem cell transplant patients. Infections in these patients may present as a sepsislike condition with infection of multiple organisms resulting in mortality greater than 80%. Recently, several adenovirus types have also been linked to obesity and adipogenesis.

Transmission of the virus may occur primarily by the respiratory route, as an aerosolized droplet or as an airborne particle, or by a fecal-oral route. Respiratory disease caused by adenovirus is usually acquired through contact with contaminated respiratory secretions, stool, or fomites. The virus is very stable and can remain viable for weeks at variable temperatures on surfaces and in liquid solutions. The incubation period for respiratory disease is 2 to 14 days and

TABLE 65.2 **Major Families of Medically Important Ribonucleic Acid Viruses**

Virus Families (in Order of Increasing Size)	Size (nm)	Envelope	Capsid Symmetry	Genome Structure	Important Members
Arenaviridae	7–10	Yes	Spherical	SS (–) Circular segmented	Lymphocytic choriomeningitis virus Lassa fever virus Lujo virus Machupo virus Guanarito virus Sabia virus Chapare virus
Astroviridae	28–30	No	Starlike	SS (+)	Gastroenteritis-causing astroviruses
Picornaviridae	~30	No	Icosahedral	SS (+)	Cardioviruses Polioviruses (coxsackie viruses) Parechoviruses, enteroviruses Hepatitis A virus Rhinoviruses
Hepeviridae	32–34	No	Icosahedral	SS (+)	Hepatitis E virus
Calciviridae	30–38	No	Icosahedral	SS (+)	Norovirus Sapovirus
Flaviviridae	40–50	Yes	Icosahedral	SS (+)	Arboviruses Yellow fever Dengue West Nile Zika Japanese encephalitis, and St. Louis encephalitis nonarboviruses: hepatitis C virus
Togaviridae	60–70	Yes	Icosahedral	SS (+)	Rubella virus Alpha viruses
Reoviridae	~70	No "Rota" or wheel-shaped virus	Icosahedral "Rota" or wheel-shaped virus	DS 11 segments	Rotavirus Colorado tick fever
Orthomyxoviridae	80–120	Yes	Spherical, pleomorphic	SS (–) 8 segments	Human influenza virus types A, B, C Swine and avian influenza viruses
Hantaviridae	80–120	Yes	Spherical, pleomorphic	SS (–) 3 segments	Hantaan (*sin nombre*) viruses
Retroviridae	100–150	Yes	Icosahedral	SS (+) diploid	Human HIV 1 & 2 Human T-cell lymphotropic virus (HTLV 1 & 2)
Coronaviridae	120–160	Yes	Helical, crown-shaped virus	SS (+)	Coronavirus (CoV) types 1–3 CoV type 4 (SARS) virus MERS-CoV, SARS-CoV-2 (COVID-19)
Pneumoviridae	100–1000	Yes	Spherical, pleomorphic	SS (–)	Respiratory syncytial virus Human metapneumovirus
Rhabdoviridae	~180 X 75	Yes	Helical, bullet-shaped virus	SS (–)	Rabies virus

Paramyxoviridae	150–350	Yes	Spherical, pleomorphic	SS (–)	Mumps Measles (rubeola) Parainfluenza viruses Respiratory syncytial viruses

DS, Double-stranded; (+), positive-sense strand; (–), negative-sense strand; *SS*, single-stranded.

3 to 10 days for gastroenteritis. Common upper respiratory tract infections caused by adenovirus include colds, tonsillitis, pharyngitis, pharyngoconjunctival fever, and sometimes croup (viral infection of the larynx). Infections of the eye and conjunctivitis often accompany respiratory infection, and in children, otitis media (ear infection) is often a complication of the respiratory disease. Lower respiratory tract infections can be quite severe in children, and adenovirus pneumonia is often fatal in infants and young children.

A unique feature of the adenoviruses is the ability to cause severe, acute respiratory disease epidemics in military recruits, often resulting in considerable morbidity and mortality. A highly effective vaccine to control outbreaks is approved for military personnel between the ages of 17 and 50 for types 4 and 7.

Adenoviruses can be detected from a variety of specimens depending on the clinical presentation and test requirements. See Chapter 64 for an overview of specimen types used for the identification of viral infections.

Direct detection of adenoviruses targets viral antigens using monoclonal antibodies (mAbs). Assay formats include immunofluorescence (IF), enzyme immunoassay (EIA), latex agglutination, and lateral-flow immunochromatographic (IC) assays. Nucleic acid amplification tests (NAATs) for adenovirus have become the most popular diagnostic method because of the reduced detection time and increased sensitivity over traditional cell culture. NAATs have been used to detect adenovirus in all specimen types. Quantitative real-time polymerase chain reaction (PCR) on plasma, peripheral blood mononuclear cells, or whole blood is used for the detection and determination of adenovirus viremia in compromised patients to predict current and disseminated disease. These assays have also been applied to other samples (such as stool) in efforts to improve care in hematologic stem cell transplant patients. Transplant centers routinely screen and monitor adenovirus viremia in patients months after transplantation.

Adenoviruses can be cultured using various epithelial cell lines, such as A-549, HEp-2, KB, and He-La cells. Growth is usually apparent in traditional cell culture 2 to 5 days after inoculation. Adenovirus produces a characteristic grapelike cluster cytopathic effect (CPE). Rapid cell culture (i.e., shell vials) using centrifugation reduces detection time but is less sensitive than conventional tube culture. A confirmatory follow-up test is performed using an indirect fluorescent antibody (IFA) technique or EIA. Culture may still be used to detect types that may be missed by direct methods or for identification and typing of novel viruses in epidemiologic studies.

Arenaviridae

Arenaviruses, of the family *Arenaviridae,* include 43 spherical, enveloped RNA viruses that have T-shaped glycoprotein spikes 7 to 10 nm long surrounding the surface membrane of the virion. The viruses can readily infect a variety of mammalian species, especially rodents and bats, often resulting in a deleterious effect on the reservoir rodent host. Human transmission usually occurs through inhalation of aerosols of infected rodent excrement (urine, saliva, feces, nasal secretions) or by direct contact with infected rodents. Ectoparasites have also been implicated in transmission to humans. Health care–related transmission has been reported for Lassa and Machupo viruses. Disease in humans has been associated with nine arenaviruses, which clinically display a broad range of symptoms, from asymptomatic (no symptoms) to fever, prostration, headache, and vomiting, to the more severe cases of meningitis and hemorrhagic fever.

Arenaviruses are classified into Old World (OW) and New World (NW) groups based upon serotyping and phylogenetic analysis. The OW arenaviruses capable of causing disease in humans include the prototypic lymphocytic choriomeningitis virus (LCMV) and the highly pathogenic Lassa fever virus (first detected in Lassa, Nigeria). LCMV has been identified in cases of aseptic meningitis in Europe and the Americas. LCMV can occur in rural and urban areas with high rodent populations and has been acquired from pet hamsters. It has also been linked to at least 10 human deaths following organ transplantation from LCMV-infected individuals. Lassa has been associated with hemorrhagic fever, shock, and death in 5% to 15% of symptomatic patients (80% of cases are asymptomatic), killing approximately 5000 people each year. Lassa fever virus is a significant cause of morbidity and mortality in West Africa, where economic resources are limited. Capillary leak and widespread organ involvement, accompanied by shock, respiratory distress, and/or hemorrhage, are responsible for most deaths from Lassa fever. Other, less commonly reported arenaviruses may also cause hemorrhagic fever, including LuJo virus, which caused a Lassa fever–like outbreak in South Africa, and Junin virus, associated with Argentine hemorrhagic fever. Isolated arenavirus outbreaks have also been caused by Machupo virus (MACV) in Bolivia, Guanarito virus (GTOV) in Venezuela, Sabia virus in Brazil, and Chapare virus in Bolivia.

Arenavirus infection is diagnosed using enzyme-linked immunosorbent assay (ELISA)-based serologic tests or reverse transcriptase polymerase chain reaction (RT-PCR) to detect viral nucleic acid. An antigen capture ELISA for the quantitative detection of arenavirus in serum and tissue culture supernatants has been used for early detection and identification. Viral isolation using cell culture is not routinely recommended. Cell culture for viral isolation has proven to be unreliable because of inconsistent sensitivity. In addition, handling cultures and specimens puts laboratory personnel at high risk. Samples and cultures containing LCMV require Biosafety Level (BSL) 3 facilities, and Lassa fever virus requires a BSL 4 laboratory. Serologic diagnosis is also difficult, because the immunologic antibody response is delayed for several days and often weeks after symptomatic illness. Multiplex RT-PCR assays have been developed to detect several arenaviruses and are becoming more widely available in the acute care or routine clinical laboratory setting.

Astroviridae

Astroviruses, so called because of their characteristic starlike surface structure, are small (28 to 30 nm), round, nonenveloped, single-stranded, positive-sense RNA viruses associated with gastroenteritis. Transmission occurs via the fecal-oral route through close contact with infected individuals or contaminated fomites. Astroviruses are more commonly associated with pediatric infections, military troops, and nursing home and immunocompromised patients. Gastroenteritis caused by astroviruses are usually mild and self-limiting. A number of antigen detection tests have been developed for the detection of astroviruses in stool but are not available for use in the United States. A multiplex NAAT, the FilmArray gastrointestinal panel (bioMerieux BioFire Diagnostics, Salt Lake City, UT) can be used to detect astroviruses from stool samples.

Caliciviridae

Caliciviruses are small (30 to 38 nm), rounded, nonenveloped, single-stranded, positive RNA viruses that cause acute gastroenteritis in humans. Caliciviruses have been previously recognized as major animal pathogens and have a broad host range and disease manifestation. The viruses cause respiratory disease in cats, a vesicular disease in swine, and a hemorrhagic disease in rabbits. Not until the 1990s did the taxonomic status of noroviruses (formerly known as Norwalk-like viruses, named after Norwalk, OH) result in classification in the family *Caliciviridae.*

Members of the *Norovirus* and *Sapovirus* genera are the primary cause of viral gastroenteritis in humans and are referred to as the **human caliciviruses** (HuCVs). Previously called "Norwalk-like viruses" and "Sapporo-like viruses," the viruses were named after their prototype strains, the Norwalk virus and the Sapporo virus, respectively. These viruses are referred to as the norovirus and sapovirus. The HuCVs are further classified into genogroups**,** and within the genogroups, into genetic clusters. Human isolates in the norovirus genogroup include genogroups I, II, and IV and in the sapovirus genogroup, I, II, IV, and V.

Roughly 685 million cases of gastroenteritis are caused by norovirus each year, making it the most common cause of acute gastroenteritis worldwide. Among these cases, approximately 200 million occur in children under the age of 5, resulting in an estimated 50,000 to 70,000 or more childhood deaths every year, mostly in developing countries. Yet the impact of norovirus infection can be felt in both low- and high-income countries, where it is a major public health concern due to its ability to cause large outbreaks in semiclosed environments, such as cruise ships, nursing homes, schools, summer camps, hospitals, and restaurants. Several factors contribute to the rapid spread of infection: fecal-oral transmission, the low infectious dose (fewer than 100 virus particles), and the virus's high environmental stability. Noroviruses are easily transmitted in food, water, person to person, or in airborne droplets of vomitus. The virus persists in water despite treatment processes. Worldwide norovirus infection is estimated to cost nearly $65 billion in direct health care costs and lost productivity every year.

Norovirus infections cause moderate to severe gastroenteritis; the clinical symptoms include nausea, abdominal cramps, vomiting, and watery diarrhea. Symptoms usually occur after a 1- to 2-day incubation period and continue for approximately 1 to 3 days. Vomiting occurs more often in children than in adults. Infection with sapovirus causes mild to moderate gastroenteritis with symptoms similar to norovirus; however, sapoviruses more frequently cause disease in infants and toddlers than in school-age children, whereas norovirus infections are common to all age groups. Maximum viral shedding in the feces occurs early, at the onset of clinical symptoms, but viral shedding can occur for up to 2 to 3 weeks after cessation of the clinical symptoms. As a result, control of viral transmission is problematic, and infection does not confer long-lasting immunity.

Norovirus cannot be cultivated using cell culture. The most widely used identification method is RT-PCR. Commercially available ELISA kits that use mAbs or hyperimmune sera are also available to detect norovirus but demonstrate lower sensitivity and specificity than RT-PCR. Multiplex NAATs, the Verigene Enteric Pathogens Nucleic Acid Test (Luminex Corporation, Austin, TX) and the FilmArray gastrointestinal panel (bioMerieux BioFire Diagnostics, Marcy I Etoile, France) can be used to detect noroviruses from stool samples. The FilmArray also detects sapoviruses.

Coronaviridae

The family *Coronaviridae* includes the genera *Alphaletovirus, Alphacoronavirus, Betacoronavirus, Deltacoronavirus,* and *Gammacoronavirus,* collectively referred to as coronaviruses (CoVs). This family contains many species of both human and animal origin. Once considered a harmless virus causing the "common cold," the CoVs cause a wide variety of disease in animals and birds. In general, CoVs are pleomorphic, roughly spherical, very large (120 to 160 nm across), enveloped linear positive-stranded RNA viruses. The prefix "corona" results from the viral structure and the crownlike surface projections on the external surface of the virus that can be seen with electron microscopy. Most of the human respiratory CoVs cause colds and occasionally pneumonia in adults. Together the rhinoviruses (RVs) and CoVs cause more than 55% of the common colds in the human population. CoVs are found in a wide range of domestic and wild mammals and birds. A variety of species and subspecies occur worldwide; they are characterized by frequent recombination and the formation of distinct genotypes.

Three specific genotypes known to infect humans belong to the genus *Betacoronavirus* and emerged as a result of recombination events and zoonotic transmission, including the severe acute respiratory syndrome–related coronavirus (SARS-CoV), the Middle East respiratory syndrome–related coronavirus (MERS-CoV) and the COVID-19, also known as SARS-CoV-2. Viral transmission is person-to-person via contaminated respiratory secretions or aerosols. The virus is present in the highest concentration in the nasal passages, where it infects the nasal epithelial cells. CoVs are believed to cause diarrhea in infants, based on the presence (as seen with electron microscopy) of coronavirus-like particles in the stool of symptomatic patients.

CoVs are generally associated with upper respiratory tract infection and occasional lower respiratory tract infection in patients of all ages. Some animal CoVs are known to cause acute gastroenteritis in humans.

Severe respiratory disease associated with CoVs is characterized by a rapid onset of high fever, followed by a dry cough and dyspnea. The severe respiratory syndrome follows an incubation period of approximately 2 to 7 days after the appearance of the initial symptoms (fever, headache, myalgia, and malaise). The illness progresses to severe respiratory distress, requiring the patient to be hospitalized for supportive care and mechanical ventilation. The period of maximum infectivity and highest viral loads in the upper airways of patients begins in the second week of illness, during the time the patients often were severely ill. This poses a high risk of transmission to health care workers during this period.

COVID-19 emerged as a new human CoV in December of 2019, when local outbreaks of a CoV-like severe respiratory disease was reported in individuals who had frequented a Hunan seafood and animal market in Wuhan, China. COVID-19 rapidly became a worldwide pandemic, with nearly 70,000 cases reported within the first month, resulting in a fatality rate of 2% to 3%. Within approximately 5 months, 185 countries worldwide reported widespread human infections with the virus, and an alarming fatality rate. SARS-CoV-2 has nucleic acid similarity to two bat-derived SARS–like CoVs of bat origin, SL-CoVZC45 and SL-CoVZXC21. COVID-19 resulted in asymptomatic to mild to severe acute respiratory disease, cardiac abnormalities, coagulopathies, and immune syndromes that posed significant treatment difficulties. Symptoms could include anything from a headache, high fevers, body aches, shortness of breath, low oxygen saturation, diarrhea, dry cough, anosmia (loss of smell), and dysgeusia (distortion of taste), As a novel virus, the race for effective treatment and a vaccine was initiated in numerous labs across the globe.

All CoVs pose a significant diagnostic challenge, with very low levels of CoV in the respiratory tract during the early phase of disease. Although antigen detection is available for some CoVs, the technique lacks sensitivity compared with nucleic acid–based testing. Molecular testing by RT-PCR remains the recommended method for laboratory diagnosis. Several commercially available multiplex assays are available for the rapid detection of the human endemic species of CoV. During the COVID-19 outbreak, the Centers for Disease Control (CDC) released an emergency use authorization (EUA) RT-PCR diagnostic panel. CDC as well as other commercial manufacturers also produced multiple RT-PCR diagnostic panels capable of detecting SARS-CoV-2, influenzae A, and influenzae B. CDC released an EUA for the detection of antibodies to COVID-19 to determine the general overall infection rate in the United States and to evaluate commercial serological tests available for laboratory diagnostics. Although nucleic acid testing by RT-PCR is the most useful diagnostic test available, the CoVs are capable of growth in cell culture using either the Vero-CCL81 or the Vero-E6 cell line. The characteristic viral CPE appears as a rapid cell rounding, refractivity, and detachment. BSL 3 or higher is required for propagation and manipulation of cell cultures containing this virus.

Throughout the pandemic treatment options for SARS-CoV-2 improved as information relative to the biology and pathology of the virus became available. No drug has been proven to be an effective therapy for COVID-19; however, several clinically available drugs were repurposed for use in treating COVID-19, and new experimental treatments were authorized by the FDA under the emergency use authorization during the pandemic. The standard of care for patients primarily focused on supportive measures, managing fever and potential preventative care using the repurposed or experimental treatments. Chloroquine and hydroxychloroquine were initially being tested as an antiviral medication in several studies. However, the therapeutic index appeared to be very narrow and several adverse effects associated with the drug including life-threatening toxicity, cardiomyopathy, arrhythmias, and hemolytic anemias were identified, and the use of the drug was terminated. Remdesivir, a nucleoside analog that inhibits viral RNA synthesis, which was developed by Gilead Sciences (Foster City, CA) for treatment of Ebola, is only available as an intravenous medication. The use of remdesivir improves the patient's respiratory symptoms when administered during either a 5- or 10-day treatment. Patients receiving remdesivir should be monitored daily for potential liver toxicity. If the patient's liver enzymes are elevated (alanine aminotransferase and aspartate aminotransferase) and continue to rise, remdesivir should be discontinued. In addition to a variety of other antiviral medications, treatments often include drugs that inhibit or reduce the effects of proinflammatory cytokines that have been associated with the development of severe pneumonia, a high risk of multiorgan failure and death. Interleukin-6 (IL-6) was identified as being 10-fold higher in patients with severe COVID-19 infection and those that were critically ill. Because most laboratories are unable to measure IL-6 levels, C-reactive protein (CRP), is used as a marker for IL-6, as IL-6 inhibitors rapidly reduce the levels of CRP. Tocilizumab, a human monoclonal antibody to IL-6, has been used to treat COVID-19, resulting in the reduced use of supplemental oxygen and improvement in clinical symptoms. The FDA also approved the emergency use of convalescent plasma in patients with COVID-19. Convalescent plasma is obtained from patients who are eligible to donate blood, have had no symptoms of COVID-19 for at least 14 days and no longer test positive for SARS-CoV-2 RNA by RT-PCR. The use of convalescent plasma demonstrated a reduction in hospital stays and reduction in mortality. In addition to these treatments, several commercial biotechnology companies actively pursued the development and manufacturing of human SARS-CoV-2 antibodies for use in clinical trials for the treatment of disease. Vaccine development and clinical trials were underway by a variety of manufacturers across the globe at the time of this writing.

The COVID-19 pandemic has posed a significant challenge to health care systems not only in the United States but throughout the global community. Health systems lacked the supply chain necessary to provide adequate personal protective equipment to health care workers, testing supplies for COVID-19 as well as general medical and diagnostic laboratory supplies and highlighted the shortage of medical laboratory science professionals. Undoubtedly, the evolution of the recent pandemic has and will continue to identify new methods and approaches to the diagnosis, treatment, and management of infectious disease now and in the future.

Filoviridae

The *Filoviridae* family of viruses currently includes five genera: the *Cuevavirus, Ebolavirus, Marburgvirus, Striavirus,* and *Thamnovirus.* Ebola virus and Marburg virus are considered the most pathogenic and virulent of all the hemorrhagic fever viruses. As a family, **filoviruses** are pleomorphic, long rodlike, enveloped, nonsegmented, single-stranded, negative-sense RNA viruses. The filamentous morphology appears in many forms or configurations, such as the number 6, U, or circular. Marburg hemorrhagic fever virus displays the characteristic “shepherd’s hook” morphology. The term **viral hemorrhagic fever** is used to describe a severe multisystem syndrome in which multiple organ systems are affected throughout the body. The patient’s vascular system becomes damaged, and the body’s ability to regulate itself is impaired. Infection with the Marburg or Ebola virus, endemic in Africa, results in severe hemorrhage, vomiting, abdominal pain, myalgia, pharyngitis, conjunctivitis, and proteinuria, and it is often fatal. Human case fatality rates for Ebola virus disease (EVD) can exceed 80%; the toll for Marburg virus infection is much lower, with a case fatality rate of 23% to 25%. These diseases have no cure or well-established drug treatment.

Ebola virus is named after a river in Zaire (now the Democratic Republic of the Congo), where it was first identified. The genus *Ebolavirus* has five subspecies, based on the location where the viral strain was first identified: *Zaire ebolavirus, Sudan ebolavirus, Tai Forest ebolavirus* (formerly referred to as *Cote d’Ivoire ebolavirus* or Ebola–Ivory Coast), *Bundibugyo ebolavirus,* and *Reston ebolavirus.* All of the Ebola subspecies cause disease in humans and nonhuman primates (i.e., chimpanzees, gorillas, and monkeys) except for *Reston ebolavirus,* which causes disease only in nonhuman primates. Infections are acute, with no carrier state, and humans become ill after contact with an infected animal, usually a primate. Transmission of the virus is rapid. Individuals caring for the sick who come in contact with the patient’s secretions quickly develop symptoms.

Ebola outbreaks have elicited worldwide response, with the World Health Organization (WHO) declaring a Public Health Emergency of International Concern. The largest outbreak occurred in West Africa (Guinea, Liberia, and Sierra Leone) in 2014 to 2015 with 28,616 confirmed, probable, and suspected cases and 11,310 reported deaths. Subsequent outbreaks have occurred in the Democratic Republic of Congo in 2017 and again in 2019, which continues to claim lives (1396 deaths among 2071 total patients, as of June 10, 2019). This outbreak appears to be spreading into Uganda.

Treatment options for EVD are limited but have increased significantly following the recent outbreaks. Supportive care, such as fluid replacement therapy, that is carefully managed and monitored by trained health workers improves chances of survival. Other treatments being used to help people survive EVD include kidney dialysis, blood transfusions, repurposed pharmaceuticals (favipiravir), mAb biologics, blood/plasma replacement therapy, and vaccines. Of the biologics, two mAb cocktails are currently in various stages of clinical trials, including ZMapp (Leafbio, San Diego, CA) and MIL 77 (MabWorks, Allston, MA) MIL 77 has already been prescribed to treat EVD patients under compassionate use guidelines. Blood/plasma replacement therapies utilize whole blood or plasma from recovered (convalescent) EVD patients and the antibodies contained therein to confer some degree of immune protection to the recipient. Phase II/III convalescent plasma and whole blood trials are ongoing in Sierra Leone and Guinea. In addition, there are at least 15 Ebola vaccines being developed and in various stages of human clinical trials, according to the WHO. The first to emerge from Phase III clinical trials is rVSV-ZEBOV (NewLink Genetics and Merck Vaccines USA in collaboration with the Public Health Agency of Canada), which works by replacing a gene from a harmless virus known as vesicular stomatitis virus (VSV) with a gene encoding an Ebola virus surface protein. Clinical trial results indicate that rVSV-ZEBOV offers substantial protection against EVD, with no cases occurring in vaccinated individuals 10 days or more after vaccination. Vaccination strategies involving rVSV-ZEBOV, although not yet licensed, are currently being used through emergency authorization to control the Ebola outbreak in the Democratic Republic of Congo. Recognizing the urgent need for a vaccine, large consortiums such as the Partnership for Research on Ebola Vaccinations (PREVAC) have been assembled to include research and academic institutions, health authorities and scientists from Ebola-affected countries, pharmaceutical companies, nongovernment organizations, and national public health officials with the goal of enhancing Ebola research activities to prevent or respond effectively to the next potential Ebola outbreak. PREVAC conducted randomized, double-blind studies of rVSV-ZEBOV with and without a boost, and another two-dose vaccination process, referred to as a **heterologous prime-boost** with Ad26, ZEBOV, and MVA-BN-Filo. The rVSV-ZEBOV is now a US Food and Drug Administration (FDA)-approved vaccine for Ebola (Johnson and Johnson, in collaboration with Bavarian Nordic).

The natural animal reservoir for the Ebola and Marburg viruses has never been determined, although the animal source is believed to be native to Africa. Disease outbreaks in monkeys have occurred in the United States in research facilities. Several monkeys housed in separate cages became ill simultaneously. Laboratory workers working in these facilities were also infected and developed antibodies but never developed symptoms of the disease. Reston ebolavirus is known to have caused infections through aerosolization of secretions.

RT-PCR is used to identify the Ebola and Marburg viruses. Electron microscopy is also available in some research facilities. Cell culture is available in laboratories with BSL 4 facilities. Antibody production occurs after an Ebola virus infection, and an antigen-capture ELISA is available to detect IgM and IgG antibodies to Ebola virus. Seven diagnostics have been approved for Emergency Use Assessment and Listing procedure (EUAL) by WHO including the OraQuick Ebola Rapid Antigen Test Kit (OraSure Technologies, Inc., Bethlehem, PA), SD Q Line Ebola Zaire Ag (SD Biosensor Inc. Gyeonggi-do, Republic of Korea), Xpert Ebola Test (Cepheid, Sunnyvale, CA), LiferiverTM Ebola Virus (EBOV) Real Time RT-PCR Kit (Shanghai ZJ BioTech Co., Ltd., Goettingen, Germany), and RealStar Filovirus Screen RT-PCR Kit (Altona Diagnostics GmbH, Hamburg, Germany).

Flaviviridae

The **flaviviruses** (family *Flaviviridae*) are small (40 to 50 nm), single-stranded, nonsegmented, positive-sense RNA, enveloped, icosahedral viruses. The name is derived from the Latin word *flavus,* which means "yellow." The first disease identified in this group was yellow fever, which causes yellow jaundice in humans. The family includes four genera: *Flavivirus, Hepacivirus, Pegivirus,* and *Pestivirus*. Most members of the genus *Flavivirus* are also known as **arboviruses**, which are arthropod-borne and primarily transmitted via mosquitoes, causing diseases such as Zika fever, yellow fever, dengue, West Nile viral encephalitis, and Japanese and St. Louis encephalitis. Hepatitis C virus (HCV) is a flavivirus but not an arbovirus.

Yellow Fever

In the jungle habitat, monkeys serve as the reservoir for the yellow fever virus, and the vector is a mosquito. In urban outbreaks, humans can serve as the reservoir, as long as the mosquito vector is present.

The yellow fever virus primarily infects liver cells, resulting in fever, jaundice, and hemorrhage. Transmission through the mosquito bite is followed by a 3- to 6-day incubation period. The onset of symptoms is sudden and includes fever, rigors, headache, and backache. The patient's clinical condition progresses rapidly, and the patient becomes intensely ill with nausea, vomiting, facial edema, dusky pallor, swollen bleeding gums, and hemorrhagic tendencies that cause black vomit, melena (black tarry feces), and ecchymoses (bruising). Mortality rates range from 5% to 50%; when death occurs, it is usually within 6 to 7 days after the onset of symptoms but rarely after 10 days. The characteristic yellow jaundice typically is seen in convalescing patients. Prevention in urban areas depends on elimination of the yellow fever vector, the mosquito, *Aedes aegypti.* The current vaccine is very effective at preventing infection.

Diagnosis of yellow fever infection is often a result of correlation of the patient's clinical symptoms with the patient's location and travel history. Laboratory testing on serum or cerebrospinal fluid (CSF) is available for detection of virus-specific antibodies or neutralizing antibodies. Serologic testing is also available using IgM-capture ELISA, microsphere-based immunoassays (MIAs), and IgG ELISA. In fatal cases of yellow fever, patient tissues may be sent to reference laboratories for nucleic acid amplification, histopathology, and cell culture. A single NAAT, the FTD Tropical Fever Africa Yellow Fever multiplex assay, is available from Mikrogen Diagnostik, Germany.

Dengue

Dengue virus is the most prevalent arbovirus in the world, with incidence rates growing dramatically in recent decades, putting nearly half of the world's population at risk. By some estimates, there are more than 390 million people infected each year, most of which are asymptomatic. Some degree of clinical disease (mild to severe) is evident in roughly 100 million of these cases. Prior to 1970, the virus was endemic only to Latin America, Puerto Rico, and Mexico, but since has expanded its range to more than 100 countries in Africa, the Americas, the Eastern Mediterranean, South-East Asia and the Western Pacific and is the leading cause of illness and death in the tropics and subtropics. Most cases reported in the United States (more than 90%) are travel related. Humans are the main reservoir for this virus, and person-to-person transmission occurs through a mosquito vector. Control methods for dengue are focused on control of the mosquito vector and early detection, which, with access to proper medical care, lowers fatality rates below 1%.

Dengue virus has four serotypes that cause a variety of clinical manifestations, including nonlethal fever, arthritis, and rash. Infection with one serotype confers immunity only to the infecting serotype. Subsequent infection with one of the three remaining serotypes may result in immune-enhanced disease in the form of severe hemorrhagic fever or dengue shock syndrome. Of the more than 390 million cases of dengue fever, 500,000 cases result in dengue hemorrhagic fever, causing approximately 25,000 deaths annually. Dengue normally affects adults and older children. The infection begins with a sudden onset of fever, severe headache, chills, and general myalgia. Often a macropapular rash may be visible on the trunk of the body that then spreads to the face and extremities. No vaccine is available for dengue, although a live-attenuated vaccine has shown efficacy in clinical trials for seropositive individuals. Laboratory diagnosis is based on the presence of virus-specific IgM antibody, a fourfold rise in specific IgG antibody, or a positive RT-PCR amplification for dengue genomic sequences. Multiple monoplex and multiplex NAATs are available for the diagnosis and detection of the dengue virus.

West Nile Virus

West Nile virus (first isolated in the West Nile district of Uganda), a flavivirus closely related to the Japanese and St. Louis encephalitis viruses, is endemic in Africa, Israel, Europe, the United States, Canada, Mexico, Central America, South America, and some Caribbean islands. The virus accounts for the largest number of cases of viral encephalitis in the United States.

West Nile virus is maintained in a bird-mosquito cycle. Birds are the natural reservoir for the virus. Many species of mosquitos and birds have been identified as being able to be infected with the West Nile virus. Amplification of virus during warm months results in the death of bird hosts, most commonly crows, ravens, and jays. Bridge mosquitos (those that bite both humans and birds) are responsible for transmission to humans; as the viral population increases in birds, more humans become infected. Interestingly, West Nile virus also has been transmitted person-to-person through blood transfusions, tissue transplantation, and via human breast milk. Infection is accompanied by fever, headache, body aches, joint pains, vomiting, diarrhea, rash, leukopenia, and/or malaise in roughly 1 out of every 5 cases, while progression to encephalitis or meningitis can occur in roughly 1 out of every 150 cases.

Laboratory diagnosis typically involves detection of IgM antibody to West Nile virus in the patient's serum or CSF. Several commercial kits are available for detection of West Nile IgM- and IgG-specific antibodies using ELISA or IFA methods. A variety of monoplex (and a single multiplex) NAATs are available for the detection of West Nile virus. Nucleic acid amplification testing has also been successful in detecting the arbovirus from the tissues of fatal cases and has also been used to detect the virus from the tissues of birds. Additionally, similar molecular testing has been used to detect West Nile virus in mosquito pools. West Nile mosquito surveillance has become increasingly important in the attempt to control this disease.

Zika Virus

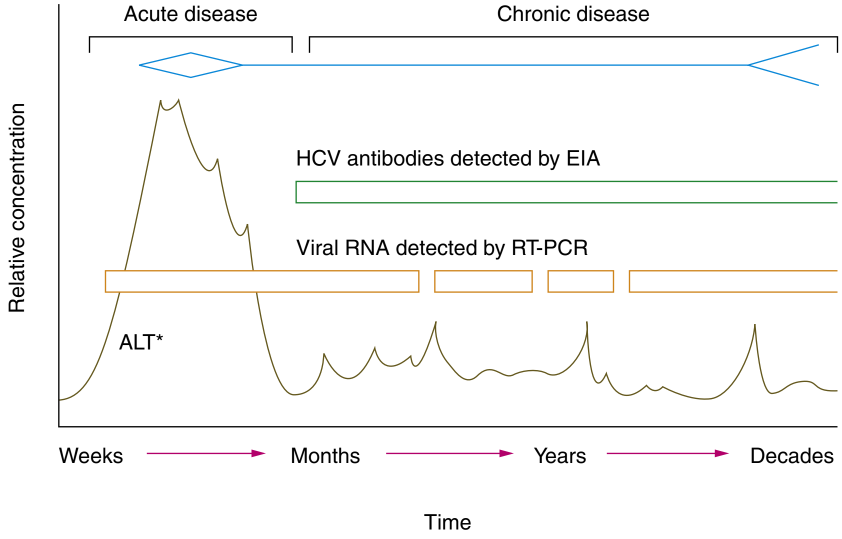
Zika virus was first identified in Uganda in 1947 in monkeys and 5 years later in humans in Uganda and nearby countries. Since then, outbreaks of Zika virus disease have occurred in Africa, the Americas, Asia, and the Pacific. In May 2015, the Pan American Health Organization (PAHO) issued an alert regarding a Zika virus outbreak in Brazil with reports of neuropathy, myelitis, and Guillain-Barre syndrome, a rare autoimmune disorder impacting the peripheral nervous system that leads to weakness, numbness, tingling, and can eventually cause paralysis in adults and children. Shortly thereafter, reports of pregnant women giving birth to babies with defects such as microencephaly and other congenital malformations (now known as congenital Zika syndrome) were linked to Zika virus; other poor pregnancy-associated outcomes were also reported. There is no specific treatment for Zika. Patients are recommended to push fluids to prevent dehydration, get plenty of rest, and take acetaminophen (Tylenol) to reduce fever and pain.

Transmission of Zika virus occurs from infected mosquitos (*Aedes* spp.), mother to fetus during pregnancy, sexual contact, transfusion of blood and blood products, and organ transplantation. Zika virus has been detected in whole blood, serum, plasma, urine CSF, semen, saliva, and amniotic fluid. Laboratory diagnosis is typically performed using whole blood, serum, and/or urine. If a patient is presenting with onset of symptoms less than 7 days, then nucleic acid testing (NAAT) is recommended. If a patient is presenting with onset of symptoms ≥7 days, then IgM serological testing and/or NAAT is recommended. When using NAAT beyond the 7-day window, negative results may be misleading, because viremia drops rapidly approximately 7 days after onset of symptoms and may not be detected by the test at the lower end of sensitivity, producing a false-negative test result. Several serologic and NAAT tests are commercially available for the diagnosis and detection of the Zika virus.

Hepatitis C Virus

The HCV causes hepatitis (inflammation of the liver). Worldwide, an estimated 177.5 to 185 million people are infected and carriers of HCV; about 2.4 million of those live in the United States. The virus can cause both acute and chronic disease, ranging in severity from a mild illness lasting a few weeks to a serious, lifelong illness. Acute infection with HCV progresses to a chronic infection in 50% to 90% of infected individuals (Fig. 65.1). The acute infection with HCV often goes undiagnosed, because it is often asymptomatic. When clinical illness is present, it is generally mild. Chronic infection with HCV is an important cause of liver disease and is associated with the development of cirrhosis (scarring of the liver), severe liver damage, and liver cancers such as hepatocellular carcinoma. There are currently no vaccines for hepatitis C. Treatment of acute disease generally involves monitoring by a physician and surveillance for chronic disease progression. Chronic hepatitis C treatments have gotten much better in recent years with more than 13 single or combination therapies currently FDA-approved. Most of these treatments involve an 8- to 12-week course of oral therapy (pills) and can cure over 90% of people with few side effects.

The virus is transmitted predominantly by exposure to infected blood, such as during intravenous drug use,



*Alanine aminotransferase marker for liver necrosis.

• **Fig. 65.1** Time course of immune response and disease caused by hepatitis C virus *(HCV). EIA,* Enzyme immunoassay; *RNA,* ribonucleic acid; *RT-PCR,* reverse transcriptase polymerase chain reaction.

needle-stick injuries in health care settings, and contaminated blood products. The screening of blood products for HCV has virtually eliminated the risk of transmission through administration of contaminated blood products. Less efficient modes of transmission include sexual contact with infected partners, acupuncture, tattooing, body piercing, and sharing of personal hygiene products that have come into contact with blood (i.e., razors and toothbrushes).

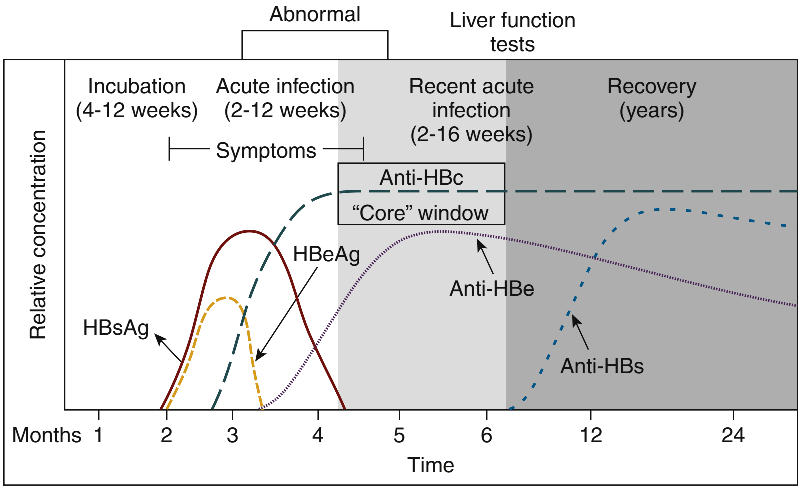
HCV disease is identified with screening antibody tests, anti-HCV EIA, and NAAT. HCV NAATs are useful for diagnosis of acute infections in seronegative patients. Chronic disease is often diagnosed using serologic screening tests followed by HCV RNA NAAT to demonstrate viral replication. In addition, quantitative NAAT is used to determine the amount of virus in the blood to monitor antiviral therapy. Finally, viral genotyping using molecular techniques is available for identifying genotypes that do not respond appropriately to therapy. The full benefits of modern laboratory testing, including the application of molecular methods, has significantly improved the recognition, monitoring, and treatment of HCV disease. A variety of serologic and NAAT platforms are commercially available for the detection and monitoring of HCV infection.

Hantaviridae

The hantaviruses, in the family *Hantaviridae*, are fairly large (80 to 120 nm) spherical or pleomorphic, enveloped, single-stranded, segmented RNA viruses. Hantaviruses were previously included in the family of *Bunyaviridae*. However, unlike the bunyaviruses, which are transmitted by arthropods (arboviruses), the hantaviruses are rodent-borne and transmitted through exposure (inhalation) to aerosolized rodent excreta. Rodents develop a chronic infection that results in shedding of the virus in saliva, feces, and urine. Disruption of animal excreta by vacuuming, sweeping, or shaking rugs aerosolizes infected particles, which are then inhaled. Evidence indicates that the chance of inhaling these particles is greater in indoor, poorly ventilated spaces than through outdoor exposure.

Hantavirus pulmonary syndrome (HPS) was originally discovered in 1993 in the Four Corners area of the southwestern United States (Arizona, New Mexico, Colorado, and Utah) during an outbreak of an unexplained pulmonary illness among several young, healthy people who died from acute respiratory failure. HPS begins with generalized symptoms that include headache, fever, and body aches, typically after an incubation period of 11 to 32 days. Subsequently, the symptoms become much more severe, leading to hemorrhagic fever, kidney disease, and acute respiratory failure. The deer mouse *(Peromyscus maniculatus)* is the primary host for the hantavirus, referred to as the *sin nombre* virus (SNV). Transmission of the virus from rodent to human is the only documented mode of human infection.

Since the discovery of SNV, several hantaviruses that cause HPS have been discovered throughout the United States. The Bayou virus, carried by the rice rat *(Oryzomys palustris),* was first identified in a patient from the state of Louisiana. The cotton rat *(Sigmodon hispidus)* is the carrier of the Black Creek Canal virus, identified in a patient from Florida. The white-footed mouse *(Peromyscus leucopus)* has been implicated in a case of a hantavirus infection called the New York-1 virus. Additional cases of HPS stemming from related hantaviruses have been documented in Argentina, Brazil, Canada, Chile, Paraguay, and Uruguay, making HPS a panhemispheric disease. Currently there is no vaccine for hantavirus, and therapeutics are only in experimental stages.



• **Fig. 65.2** Time course of antigenemia and immune response in a patient demonstrating recovery from acute hepatitis B *(HB)* infection.

Laboratory diagnosis relies on the identification of hantavirus using a NAAT from serum, whole blood, bronchoalveolar lavage fluid, or tissue. Hantavirus RNA is generally detectable within 3 to 10 days following the development of symptoms. The circulation of variation RNA genome types in any geographic location can complicate the use of NAAT. In order to address this, the CDC has developed a pan-hantavirus assay that is capable of detecting the highly conserved genomic L segment. This is only useful in genetically similar species and only during the acute phase of the illness during viremia. Viral RNA may be undetectable by the time the patient is hospitalized.

In addition to NAAT, diagnosis also relies on the use of serologic assays for hantavirus-specific IgM or IgG antibody. By the time symptoms have appeared, all patients have formed hantavirus-specific IgM antibody, and most have also developed hantavirus-specific IgG antibody. ELISA is usually the method of choice for diagnosis. The assay is available at the CDC, many state public health laboratories, and some commercial reference laboratories.

Hepadnaviridae

Hepatitis B virus (HBV) is the prototype virus of the *Hepadnaviridae* family (*hepa-* from hepatitis and *dna* from the genome type). The virus has long been recognized as a significant cause of liver damage associated with morbidity and mortality. Other mammalian and avian hepadnaviruses are known to exist. **Hepadnaviruses** are pleomorphic, enveloped viruses containing circular, partially double-stranded DNA that replicates through an RNA intermediate. Replication occurs by means of reverse transcription and then DNA replication.

Although a successful vaccine against HBV exists, the number of humans infected with HBV worldwide is nearly 400 million, and approximately 50 million new cases occur annually. Humans are the only source of the virus. Percutaneous exposure to blood or blood products is the primary route of transmission. However, the virus may also be contracted through perinatal or sexual contact. HBV is a relatively heat-stable virus and can retain its infectivity in drying blood and other bodily fluids for several days. HBV infection previously was associated with blood transfusion, but this is now rare because of the routine screening of blood products and widespread vaccination program.

The incubation period for an acute HBV infection usually is 1 to 3 months but may be considerably longer. The initial symptoms of acute infection often are nonspecific, much like mild, flulike symptoms (Fig. 65.2). Many cases are asymptomatic, especially in children. The infection presents as an acute or chronic hepatitis with a pathologic effect on the liver, resulting in self-limited or fatal outcomes. Fatal disease is most likely to occur in people coinfected with the hepatitis D virus (delta agent), a deficient RNA virus capable of replication in cells infected with HBV. Chronic HBV infection remains a significant worldwide cause of liver cirrhosis and hepatocellular carcinoma despite the availability of an effective vaccine.

Because of the generality of HBV symptoms and the similarities it shares with other causative agents of hepatitis, clinicians rely extensively on the laboratory for confirmation of the clinical diagnosis of acute or chronic infection and identification of the virus. Laboratory diagnosis typically uses a combination of NAAT and immunoassays. Several commercial types of serologic and NAAT tests are available. Immunoassays are available for specific identification of viral antigens or antibodies (viral markers) in a patient's blood. The most common type of immunoassay uses the EIA format. Most of the commercially available serologic assays demonstrate excellent specificity and sensitivity. HBV is not cultivatable *in vitro.*

Hepatitis B surface antigen (HBsAg) is the most reliable marker for identifying HBV infection. The antigen becomes evident in the patient's serum weeks before any biochemical evidence associated with liver damage (biochemical liver assays may show only minimal elevation). HBsAg remains in the serum during the acute and chronic stages of hepatitis B. The presence of HBsAg 6 months after acute infection indicates that the patient is a chronic carrier. IgM (anti-HBcAg) to hepatitis B core antigen (HBcAg) appears early in the course of disease, during the acute infection. Anti-HBsAg (antibody to surface antigen) indicates the patient is in convalescence or previously vaccinated and has developed immunity. The presence of HBeAg (hepatitis B e antigen) indicates high infectivity and a chronic carrier state.

The best indication of active viral replication and a high state of infectivity is the presence of HBV DNA in the serum. Viral DNA may be detected by a number of NAATs, including PCR. A number of user-friendly molecular assays that provide a quick turnaround time are widely available and are characterized by high analytical sensitivity and specificity. Also, detection of HBV DNA in serum is used to resolve questionable serologic results. Quantitation of viral DNA is helpful in the initial evaluation of the patient's condition and for predicting the patient's response to treatment. Molecular methods for the detection and quantitation of HBV DNA differ significantly in the limit of detection, dynamic range, and detection method used. The WHO established an International HBV DNA standard to improve the standardization of the diagnostic assays and results.

Hepeviridae

Hepatitis E virus (HEV) is the type species of the genus *Hepevirus* in the family *Hepeviridae*. Previously classified in the family of caliciviruses, HEV is a small (32 to 34 nm), nonenveloped virus with a single-stranded RNA genome. There are four other members of this virus family known to cause enlarged liver and spleen disease in chickens, pigs, wild boar, monkeys, and rodents. Several genetic and antigenic variants or strains of HEV exist and are referred to as genotypes. The different viral strains are common to different geographic locations. Genotype 3 is the strain found in the United States. HEV has also been isolated from swine worldwide and from wild deer in Japan. HEV is not endemic in the United States and other developed areas of the world.

The primary mode of transmission is the consumption of water contaminated with animal feces. There is a potential for transmission from animals to humans, also known as zoonotic infection. HEV infection results in an acute and generally self-limiting viral hepatitis. Infection typically begins with nonspecific symptoms common to many viral illnesses, such as fever, headache, nausea, and stomach pain. The first signs of a potential hepatitis infection are dark urine, pale feces, and yellow discoloration of the skin and sclera (i.e., jaundice). However, not all patients develop jaundice. The liver of infected individuals typically is enlarged and tender. Most infected patients do not progress to a long-term carrier status.

This virus is well established in developing countries as a cause of hepatitis clinically similar to infection with the hepatitis A virus (HAV). It differs from HAV in that the virus can cause an exceptionally high fatality rate among pregnant women. Fulminant hepatitis develops rapidly and is fatal in approximately 30% of women when infected during the third trimester of pregnancy. The reason for this high rate of mortality among pregnant women is not known. Women should take all possible precautions to avoid exposure to HEV while pregnant, including refraining from traveling to areas of the world where HEV is endemic, such as India and Pakistan.

Two vaccines for HEV have been developed; however, only one, HEV 239, is licensed for use in humans; it is currently only available in China. The three-dose vaccine has been shown to demonstrate protective antibodies across all HEV genotypes and is 97% effective in preventing symptomatic acute hepatitis.

Clinical diagnosis of HEV infection is important not only to control outbreaks but also for clinical management of the disease. During patient diagnosis, it is imperative to rule out the other types of hepatitis that can cause a more serious form of disease. With HEV infection, liver function tests (LFTs) typically demonstrate increased levels of serum bilirubin, aspartate aminotransferase (AST), and alanine aminotransferase (ALT) at the time of disease onset. Detection and quantification of HEV RNA in blood, stool, and other body fluids is considered the "gold standard" for the diagnosis of acute infection. There are a variety of NAATs commercially available for the detection and quantification of HEV RNA. The diagnosis can be confirmed using serologic testing. High levels of both IgM and IgG antibodies are produced at disease onset. Although the high levels of IgG confer lifetime immunity to those infected with hepatitis A, whether the antibodies produced in HEV infection do the same is not known. A variety of commercial immunoassays are available that vary in sensitivity and specificity, primarily because of the antigenic variability of the virus. Cell culture systems for HEV are rare and limited to genotype 3 and 4 strains. Cell culture systems are used for research studies and are not used in clinical diagnostics.

Herpesviridae

The *Herpesviridae* family includes nine different viruses capable of infecting humans. The word *herpes* is derived from the Greek word meaning "to creep" and was historically used to describe the spreading, ulcerative skin lesions typically seen in a herpes simplex virus (HSV) infection. **Herpes viruses** are large (120 to 300 nm), double-stranded DNA, enveloped, icosahedral viruses. The virion consists of four components: the nucleic acid core, the capsid, the tegument, and the envelope. The **tegument,** an asymmetric structure made of a fibrous material, surrounds the capsid and contains 20 different proteins. These proteins enter the host cell upon fusion of the envelope and cell membrane and initiate the viral replication cycle.

Nine human herpes group viruses have been described. Herpes viruses are widely disseminated among animal species. However, the zoonotic forms of most herpes do not infect humans, except for herpes B virus from nonhuman primates. Herpes B virus causes a severe, usually fatal encephalitis in humans. Human herpes viruses (HHVs) include HSV types 1 and 2 (HSV-1 and HSV-2), varicella-zoster virus (VZV), Epstein-Barr virus (EBV), and cytomegalovirus (CMV). More recently detected herpes viruses include HHV types 6 (HHV-6), 7 (HHV-7), and 8 (HHV-8). HHV-6 and HHV-7 are lymphotropic viruses acquired early in life. HHV-8, Kaposi sarcoma–associated herpes virus (KSHV), causes a tumor of the connective tissue. HHV-6 and HHV-7 are associated with the childhood disease roseola (**exanthem subitum**). The disease is characterized by a short period of fever and a skin rash.

A unique feature of the herpes virus family is their hallmark characteristic of latency, or the virus's ability to reside in the infected host while staying in a repressed state. Reactivation of the virus can be caused by various stimuli, including fever, emotional stress, exposure to ultraviolet (UV) light, or axonal injury. Recurrence of viral replication at subsequent times results in disease that may be present differentially as a result of the host's immune response. Viruses in this family are capable of viral recurrence or reactivation. HSV-1 may reactivate, causing mucous membrane disease or life-threatening encephalitis. Encephalitis caused by HSV is the most common viral encephalitis, with 2.3 million cases reported annually. HSV-2 reactivates, causing mucous membrane vesicles or aseptic meningitis. VZV reactivates as localized lesions (shingles). EBV reactivates, causing asymptomatic shedding of virus in the oropharynx or as disseminated disease in immunocompromised patients. As does EBV, CMV recurs symptomatically in compromised hosts as a pathogen in many tissues (e.g., heart, gastrointestinal tract, lung, brain). HHV-6 and HHV-7 also cause reactivation disease in compromised hosts.

Herpesviruses

HSV-1 and HSV-2 share several viral characteristics, including a variable host range, a short replication cycle, rapid spread in cell culture, efficient destruction of infected cells, and the ability to establish latency in the sensory ganglia of the central nervous system (CNS). These viruses affect individuals of all ages and are the cause of a wide variety of disease, including mucous membrane and skin lesions and ocular, visceral, and CNS disease. HSV-1 and HSV-2 are transmitted during close personal contact; HSV-1 infection occurs at the oropharyngeal mucosa and genital sites, and HSV-2 infection occurs at genital sites. The clinical presentation of primary genital HSV-1 cannot be distinguished from HSV-2. Primary HSV-1 infection usually occurs by the time a child reaches the age of 5 years, and more than 50 million people in the United States are believed to have oral herpes. A subset of primary infections, approximately 10% to 15%, actually result in clinical disease.

The defining characteristic associated with herpes infection is the recurrence of ulcerative anogenital skin lesions after the primary infection. More than 50% of infected individuals have a recurrent episode of a lesion outbreak within 1 year after initial infection. HSV-1 is associated with mucosal lesions that resemble small vesicles that last 4 to 7 days. The lesions from HSV-1 and HSV-2 are referred to as **herpes labialis, facialis,** or **febrilis; orolabial lesions** are commonly referred to as cold sores or fever blisters. In women, HSV-2 produces vesicles on the mucosal membranes, labia, and vagina. In men, vesicles form on the shaft of the penis, the prepuce (foreskin), and the glans penis. Systemic symptoms often accompany the primary infection in women, including fever, headache, malaise, and generalized myalgias.

HSV-1 is the most commonly reported viral CNS infection and usually occurs as a result of viral neurotropic spread through the olfactory bulb. This type of infection often occurs in infants and immunocompromised patients. Without treatment, mortality rates associated with HSV infection may be as high as 80%. After appropriate treatment, the mortality rate typically is reduced to 15% in newborns and 20% in other patients. Even when treated, individuals who survive often suffer neurologic, lasting effects, experiencing difficulties in memory, cognition, and personality disorders.

Laboratory diagnosis of herpes infection is available using a variety of diagnostic methodologies. The virus can be detected using direct antigen testing or nucleic acid amplification assays (PCR) and paired serologic assays of acute and convalescent serum specimens. Direct antigen detection is a rapid, sensitive, and an inexpensive method for diagnosis. The antigen present in the lesion is mixed with HSV-specific antibody. If the viral antigen is present, it forms a complex with the antibody that can be identified using IF or immunoperoxidase (IP) staining. Immunostaining methods are less expensive than culture and DNA amplification and require less expertise than culture. This same type of reaction can be applied in an immunoassay, usually ELISA. Immunoassay offers the additional benefit of adaptability to automation.

Nucleic acid testing for the herpes virus is more widely used and is more sensitive than cell culture and antigen detection. Molecular amplification can be especially beneficial for rapid diagnosis and treatment of herpes viral encephalitis. Both qualitative and quantitative molecular assays are commercially available from a variety of manufacturers for the identification and diagnosis of herpes viral infection.

Cell culture success is highly dependent on the sample collection procedure and the quality of the specimen. The herpes lesion or vesicle should be punctured, and the vesicular fluid absorbed with a swab, making sure to swab the base of the vesicle. Samples should be inoculated into cell culture within 1 hour after collection. If this is not possible, the swab should be placed in viral transport media and either refrigerated (4°C) or frozen at −70°C to preserve the specimen until it can be properly processed and inoculated into cell culture. Herpes is readily grown in cell culture using A-549, MRC-5, or Vero cell lines. The virus is fast-growing and typically produces a characteristic rounding, refractile CPE within 5 days using traditional cell culture and 1 to 2 days using shell vial culture after inoculation. The use of either cell culture method has been replaced in most laboratories by NAAT methods.

The herpes B virus is very similar to HSV and is generally detectable as soon as 6 hours post-infection. The virus is transmitted to humans via animal bites, mucosal or eye exposures, breaks in the skin, needle sticks, and potentially through contaminated aerosols. Symptoms of infection occur within 3 to 5 days including a vesicular lesion, erythema, edema, lymphangitis, and lymphadenopathy. This is followed by fever, myalgia, vomiting, cramping, and neurologic symptoms that progress to paralysis, respiratory distress, seizures, and death in 10 days to 6 weeks. NAAT is the preferred method of diagnosis. Antibodies to herpes B virus cross-react with HSV-1 and HSV-2, requiring careful interpretation if used for diagnosis. Herpes B virus can be cultivated in monkey kidney and chick embryo cells and demonstrates CPE similar to HSV.

Varicella-Zoster Virus

VZV causes a classic childhood disease, chicken pox, and is characterized by the appearance of a maculopapular rash. Before the introduction of the vaccine for VZV, more than 90% of the adults in the United States demonstrated immunity to VZV as a result of childhood infection. Virus transmission is increased during the inclement months, because individuals are typically in close proximity, spending more time indoors. The virus is transmitted person to person via respiratory secretions.

VZV infects the conjunctiva or mucosa of the upper respiratory tract and then travels to the lymph nodes. Four to 6 days after the initial infection, infected T cells enter the bloodstream and cause a primary viremia. The infected T cells invade the liver, spleen, and other organs, causing a second round of infection. A secondary viremia ensues, 14 days after the initial infection. This secondary wave infects cells in the skin, causing the characteristic vesicular rash of chicken pox. Symptoms at the onset of infection are usually general and include fever and malaise that appear before the onset of the maculopapular rash on the patient's trunk and scalp. The lesions usually crust over in 1 to 2 days but do not resolve for approximately 3 weeks. After the acute viral replication in the skin, VZV affects the sensory ganglia in the CNS, where it establishes latency; that is, the virus "hides" in the CNS, which is not subject to vigorous immune surveillance. After a period of latency, the virus may initiate another acute infectious cycle. This reactivation produces the characteristic recurrent disease known as **shingles,** which occurs predominately in immunocompetent people older than 45 years. Shingles follows an anatomic route around the torso along the dorsal ganglia as the virus spreads cell to cell along the neurons to epithelial cells in the skin. This condition results in vesicular lesions similar to those produced during the primary infection. Shingles may be accompanied by a painful condition known as **postherpetic neuralgia**. This condition causes a chronic, debilitating pain that can persist long after other symptoms of shingles have resolved. This pain is believed to be caused by VZV destruction of neurons.

Laboratory diagnosis is not recommended for uncomplicated cases of VZV infection in healthy children or adults. However, in certain situations, such as infection in an immunosuppressed patient or neonate, laboratory diagnosis of VZV may be beneficial.

The virus produces inclusions and giant cells. The traditional method for identifying VZV was to scrape the base of a fresh vesicular lesion and stain the scrapings with Tzanck, Giemsa, or hematoxylin-eosin stain to identify the inclusions or giant cells. This method is complicated by the fact that HSV also produces inclusion bodies. An additional rapid method for identification of VZV is direct identification of viral antigens. Samples of vesicle epithelial cells are collected, and smears are prepared and stained with fluorescent, dye-conjugated, mAbs to VZV and then observed with a fluorescent microscope. This is a fairly rapid method, because it can be performed within hours of receiving the specimen. However, interpretation and sensitivity can be questionable if not enough epithelial cells are collected.

VZV can grow in cell culture. The virus produces a characteristic CPE of small clusters of ovoid cells in fibroid cells such as MRC-5, HF, and A549. However, the virus grows slowly, and positivity of the culture may take 7 to 10 days. Shell vial cultures are a simplified method of detecting VZV compared with regular cell culture. Shell vials use cover slips with MRC-5 cells attached in a monolayer across the surface. After inoculation, the cover slip is fixed with acetone after 3 and 6 days of viral growth. The cover slip is stained with fluorescein isothiocyanate–conjugated (FITC) monoclonal IgG antibody specific for VZV. Positive specimens exhibit a cytoplasmic, apple-green fluorescence when viewed under a fluorescent microscope. Serologic assays for VZV IgG and IgM antibodies are also available to determine the patient's immune status. Several commercial ELISAs are available for detection and quantitation of VZV antibodies.

Molecular diagnostic testing for VZV has become the standard platform for the detection and diagnosis of VZV disease, replacing conventional methods of identifying the virus. It is especially useful in the rapid diagnosis of neurological disease associated with VZV, including cerebellitis, aseptic meningitis, and encephalitis. Molecular methods can detect multiple HHVs in a single clinical specimen using multiplex PCR. Multiple NAAT VZV assays are commercially available including multiplex automated DNA microarray methods for high-throughput detection of multiple herpes viruses, including VZV, in clinical samples. Molecular diagnostics also can quantitate viral VZV DNA in the blood. Molecular testing is useful for monitoring patients considered high risk for severe VZV infection.

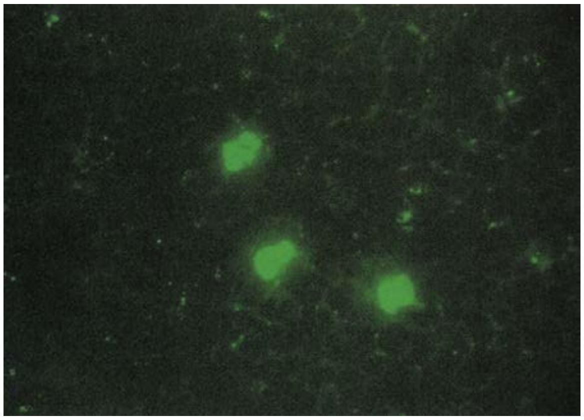
Epstein-Barr Virus

EBV was discovered four decades ago during a search for the cause of Burkitt lymphoma, a disease that predominately affects children in Africa. EBV is responsible for the disease **infectious mononucleosis (IM).** The virus, which is transmitted in the saliva of infected patients, typically affects adolescents and young adults. The major symptoms include fever, sore throat, headache, malaise, and fatigue. Lymphadenopathy (swollen lymph nodes) and splenomegaly may occur during the disease. Mononucleosis typically is diagnosed through serologic methods that detect antibodies to EBV (Fig. 65.3). Nonspecific heterophile antibodies (also referred to as **Paul-Bunnell antibodies**) appear early on during the disease, making the diagnosis difficult. Antibody production to the virus typically follows the classic immune response, resulting in specific IgM production followed by IgG production. Antibody (IgM) to the **viral capsid antigen (VCA)** appears within 4 weeks after infection. This is followed by IgG and IgA antibody to the **early antigen (EA)**, indicating acute or recent infection. Both the EA-IgG and IgA may be undetectable after approximately 6 months. Some Anti-EA IgG antibodies may persist in the patient's serum for life. These persistent antibodies typically are elevated in patients with Burkitt lymphoma. The final diagnostic serologic marker is the antibody to the **nuclear antigen (EBNA)** that appears within 1 month of infection and peaks approximately 6 to 12 months after infection. In addition to Burkitt lymphoma, other cancers have been associated with EBV infection (e.g., nasopharyngeal carcinoma). EBV is recognized as an important agent in the development of lymphoma or other lymphoproliferative disorders in transplant recipients.

Molecular assays have become instrumental in the diagnosis of herpes viruses. A variety of EBV DNA assays are available commercially. The method and sample matrix used is dependent on the suspected clinical syndrome. Quantitative assays for the detection and diagnosis of EBV infection are preferred over qualitative in order to determine the risk for the patient in progressing to EBV-associated disorders. Detection of EBV DNA and microRNAs (small noncoding RNAs involved in gene regulation) in nasopharyngeal brushings has been used for the diagnosis of EBV associated nasopharyngeal carcinoma. The prediction for the development of EBV-associated post-transplant lymphoproliferative disorder (PTLD) can be determined by monitoring EBV DNA loads shortly after transplantation. Monitoring viral loads and reducing immunosuppressive medications has reduced the incidence of EBV associated PTLD. In order to assist in the standardization of molecular methods for the detection and monitoring of EBV DNA, the WHO approved the use of a whole EBV preparation that was created by the National Institute of Biological Standards and Controls, United Kingdom.

Cytomegalovirus

CMV infection is a common cause of congenital birth defects. The virus is included in the TORCH panel for disease screening in infants. (TORCH is an acronym for toxoplasma, rubella, CMV, and HSV-1). Besides being the cause of congenital infection in infants, CMV has been found to cause an IM–like illness in immunocompromised patients. The disease can be extremely serious in immunosuppressed organ transplant recipients. CMV can be identified using viral cell culture, serologic tests for IgM and IgG antibodies, direct antigen detection, and nucleic acid testing. Although the virus grows in cell culture using human fibroblasts, it is a slow-growing virus that requires 1 to 2 weeks of incubation before CPE is evident, providing a diagnosis within 24 to 48 hours. CMV antigenemia (Chapter 64 and



• **Fig. 65.4** Typical fluorescing white blood cells containing cytomegalovirus (CMV) antigen, as seen in the CMV antigenemia stain.

Evolve Procedure 64.2) is routinely used to monitor therapy for CMV infection. A positive CMV antigenemia result is shown in Fig. 65.4.

Molecular qualitative and quantitative PCR amplification have replaced the antigenemia assay in most clinical laboratories. A variety of assays are available for the detection of CMV DNA and mRNA in both monoplex and multiplex panels. NAATs are used for the identification and detection of CMV DNA in immunocompromised patients, including patients with acquired immune deficiency syndrome (AIDS), transplant recipients, and patients with congenital infections, as well as for monitoring the efficiency of antiviral therapy. Viral load measured using CMV DNA is considered the best predictor for the development of CMV-associated disease. Comparative analyses of CMV antigenemia and CMV DNA quantitation demonstrate general agreement when used to monitor disease syndromes.

Orthomyxoviridae

The influenza virus is a member of the family *Orthomyxoviridae*. The **orthomyxoviruses** are large (80 to 120 nm), pleomorphic, spherical, enveloped, single-stranded, segmented, negative-sense RNA viruses. Of all the respiratory viruses known to infect humans, influenza is the cause of the greatest number of serious acute illnesses; more than 200,000 hospitalizations and more than 30,000 deaths occur in the United States every year. Although three types of influenza viruses are known to infect humans (A, B, and C), type C usually causes subclinical infections or mild respiratory disease. Influenza virus A, influenza virus B, and influenza virus C can be distinguished based on the antigenic differences in the **matrix protein (M)** and the **nucleoprotein (NP).** Influenza virus A is further subdivided based on the major surface glycoproteins, **hemagglutinin (HA)** and **neuraminidase (NA).** Influenza A naturally infects many bird species, swine, seals, felines, and horses. Influenza B and C are only known to infect humans.

Projecting from the envelope of the virion are the two major surface glycoproteins, HA and NA. The HA proteins are rod-shaped spikes that enable viral attachment to sialic acid–containing cellular receptors. Once attached to the receptors, the virus can initiate infection. The NA proteins are mushroom-shaped spikes. They facilitate the release of mature virions from infected cells and assist in viral movement through mucus to adjacent cells. Eighteen different HA molecules and 11 different NA molecules have been identified. All of the different viral protein antigenic types can be found in the avian species. Various subtypes of both influenza A and B can cause global epidemics and pandemics following the emergence of a novel HA strain that can be transmitted readily from person to person. One example, influenza A H3N2, is a highly pathogenic virus. Infection with H3N2 results in greater mortality than infection with influenza A H1N1 or influenza B.

A unique property of influenza A and influenza B is the organization of the viral genome. It is composed of an eight-part, segmented RNA genome, each segment essentially serving as a single gene. This property, combined with the influenza viruses' unique ability to alter their HA and NA antigens, results in the production of an antigenically different virus from year to year. This is termed antigenic drift. Antigenic drift is a continuous, gradual form of change in the viral genome during replication. Antigenic drift occurs in all viral influenza types.

Influenza A undergoes a seasonal antigenic drift every year, making the formulation of an effective vaccine challenging. Antigenic shift is a much more dramatic change in the viral genome and only occurs with influenza A viruses. Antigenic shift occurs when a circulating influenza A strain acquires a completely new, or novel, subtype. This phenomenon occurs when two different strains of influenza virus simultaneously infect a single host. During viral replication the segmented genome of the influenza virus may reassort, mixing segments from the different strains during the infection, resulting in a unique antigenic combination. Avian influenza and human influenza reassortment of genes have been the cause of several pandemics throughout history. Often swine act as the intermediate, or "mixing vessel," for these reassortment events. Viruses from avian and human origin can infect and replicate in the swine respiratory epithelium. When these reassortments occur, a virus emerges against which the population does not have immune protection because of the new antigenic structure. When this happens, a pandemic (global outbreak) can occur if the virus is able to sustain human-to-human transmission. Often pandemics result in high rates of human mortality with significant social, infrastructure, and economic consequences. Enhanced surveillance for the pandemic strain of influenza H1N1 was preceded by the appearance of the avian influenza, commonly referred to as the "bird flu," circulating in Asia. This influenza strain stems from the avian population. The influenza virus (H5N1) is a highly pathogenic avian influenza that has reassorted multiple times with other avian influenza strains capable of causing disease in poultry and other birds. Despite the high prevalence of H5N1 among avian populations, human infection remains low, and the low transmissibility suggests a natural barrier to cross-species infection. Most human infections are acquired as a result of contact with infected poultry raised inside or outside the home. The case fatality rate for this disease is close to 60%. This virus has significantly affected the worldwide economy. It has caused the death and destruction of more than 500 million wild and domestic birds worldwide and resulted in losses to the poultry industry of more than $10 billion. Other avian influenza A virus subtypes are also of concern, including H7N7 in commercial poultry farms in the Netherlands, which has been associated with respiratory illness. H7N9 has emerged in poultry markets in China and has been associated with human infections.

Influenza normally is transmitted person to person through inhalation of aerosolized droplets of infected secretions. The incubation period is 1 to 4 days, with rapid onset of symptoms, including fever, nonproductive cough, sore throat, rhinitis, headache, malaise, and myalgia. The illness usually resolves within a week, although some symptoms may persist longer. Gastrointestinal symptoms, including watery diarrhea, vomiting, and abdominal pain, may occur in the absence of respiratory symptoms.

Bacterial coinfections are common with influenza, possibly because of viral NA-induced changes in the respiratory epithelium that allow increased bacterial adherence or decreased mucociliary clearance. Clusters of fatal methicillin-resistant *Staphylococcus aureus* (MRSA) infections secondary to seasonal influenza A have been reported in otherwise healthy children and adults.

Testing for influenza can be completed by viral culture, detection of viral nucleic acid or antigen, and serology. Optimal testing requires proper collection and timing of specimens, and both high-throughput and point of care testing is available. Virus is shed 3 to 5 days after the onset of symptoms. Optimal specimens are collected from the posterior nasopharynx. The epithelium of the nasopharynx usually contains high titers of virus and large amounts of infected cells. A variety of other respiratory samples, including nasal aspirates, nasal wash, throat swabs, and throat washes, may be used for viral identification. The samples should be placed in viral transport media and may be stored at 4°C for up to 5 days. If the sample must be stored longer, it should be stored in a freezer at −70°C until processed.

RT-PCR is the new gold standard for the identification of respiratory viruses. The technique is effective when specimens are compromised, such as when they are collected late in the course of the disease or when appropriate collection and transportation requirements have not been met. Sensitivity has proven to be equal to or better than that of cell culture. A variety of NAATs are commercially available for the identification and characterization of influenza A, B, and C. In addition, multiplex respiratory panels are also available that include influenza A, B, and various subtypes. However, multiplex assays may demonstrate reduced sensitivity in comparison to monoplex assays. DNA microarray assays have been developed to identify and differentiate viral subtypes; however, they are expensive, and are only available in specialized laboratories.

Cell culture is available for influenza virus using a variety of cell lines. Primary monkey kidney (PMK) cell lines and Madin-Darby canine kidney (MDCK) cell lines have demonstrated a consistent season-to-season isolation frequency of influenza virus. Sometimes the influenza viruses fail to produce a CPE in traditional cell culture, requiring additional testing by hemadsorption with guinea pig red blood cells (RBCs) for viral detection. Cell cultures are reviewed every 1 to 3 days and screened by hemadsorption. Cells that demonstrate 4+ CPE can be used for further characterization. Follow-up confirmatory methods include immunofluorescent assays (IFAs). Rapid shell vials can be used to detect virus in 24 to 72 hours, using type-specific mAbs. Shell vials cannot be used to produce virus for subsequent viral studies.

Papillomaviruses

Papillomaviruses are small (~55 nm), nonenveloped, circular, double-stranded DNA viruses. These viruses are abundant in nature and cause infections in humans, dogs, cattle, monkeys, and many other species. The *Papillomaviridae* family includes the HPVs. HPVs cause human warts. They exhibit a tissue tropism for either cutaneous or mucosal tissue. The viruses have not been cultivated in cell culture, which prevents the production of type-specific antigens and corresponding typing antisera. HPVs are divided into more than 200 genotypes based on the viral DNA sequences. Much attention has been focused on the more than 40 sexually transmitted genotypes and their role in the pathogenesis of cancer. The International Agency for Research on Cancer has designated 12 HPV types as oncogenic or high risk for the development of cancer. The various HPV genotypes have differing cellular tropisms, resulting in defined variation in the clinical presentation of the warts. For example, HPV-1 is associated with plantar warts; HPV-2 and HPV-4 are associated with common warts of the hands; and HPV-6, HPV-11, and others are associated with genital warts. Anogenital warts are associated with HPV types 6 and 11 and rarely associated with cancer. HPV types 6 and 11 are also associated with oral and upper respiratory tract warts. Oral and respiratory warts can be associated with cancer. Morbidity does occur in nonmalignant cases due to the need for surgical removal, damage to vocal cords, and potential respiratory obstruction. HPV high-risk genotypes cause cervical, vulvar, vaginal, squamous cell oropharynx, anal, and penile cancer. Approximately 95% of all cervical cancers are HPV positive. HPV-16 and 18 cause more than 70% of the cases.

HPV infection is the most prevalent sexually transmitted viral disease in the United States. Infection is detected using histopathologic or cytologic examination of cutaneous biopsy or cells, respectively, and DNA probe assays for identification of specific genotypes in infected epithelial cells. A single, liquid-based cytology sample can be used for cytology and genotyping. NAATs are used for screening and the management of cervical disease. Several commercial nucleic acid–based HPV assays currently are commercially available in the United States. The assays vary in the method of amplification, signal or target; the detected nucleic acid, RNA or DNA; the level of genotyping included in the assay; and the level of technical complexity. There are currently no commercial assays available to monitor viral load for HPV. The quantification is difficult to reproduce due to the variation in viral copy number (amount of nucleic acid) unevenly distributed throughout the tissue. Next-generation sequencing of HPV is available in research laboratory settings. However, to utilize this technology in clinical applications advances in the HPV consensus sequence and database management (bioinformatics) is required and has the potential to improve HPV diagnosis and management in the future. Three vaccines for HPV are currently licensed by the FDA: Cervarix (Glaxo Smith Kline, Brentford, Middlesex, United Kingdom), Gardasil, and Gardasil-9 (Merck & Co., Inc, Whitehouse Station, NJ), all of which protect against the two most common carcinogenic types, HPV 16 and 18. Gardasil also protects against HPV types 6 and 11, which are responsible for more than 90% of anogenital warts. Gardasil-9 further protects against several lower-risk HPV types (31, 33, 45, 52, and 58) known to be associated with cervical and most HPV-induced oral cancers.

Paramyxoviridae

The *Paramyxoviridae* family includes many pathogenic viruses. Many of these viruses are identified more often in young children, including measles, mumps, Nipah virus, and parainfluenza viruses. **Paramyxoviruses** do not have a segmented genome, as do the orthomyxoviruses, and therefore do not undergo antigenic shift. Paramyxoviruses are large (150 to 350 nm) pleomorphic, spherical or filamentous, enveloped negative-sense, single-stranded, RNA viruses, and all members of this group can cause respiratory disease.

Human parainfluenza viruses are important pathogens in children. Viral infection may present as either croup or other upper respiratory diseases in children and adults. The paramyxoviruses are second only to respiratory syncytial virus (RSV) in causing bronchiolitis and pneumonia in infants and young children. The parainfluenza virus has four subtypes; parainfluenza 1 is the most common cause of croup, and parainfluenza 3 is second in prevalence to RSV as a disease of infants and very young children. Most children have had an infection with parainfluenza 3 by 2 years of age. Parainfluenza 3 is most often associated with severe disease and fatalities. Parainfluenza 4 causes all of the same respiratory infections associated with the other types, except croup. Parainfluenza 1 and 3 are also associated with severe pulmonary infections in adults, often requiring hospitalization. Parainfluenza viruses are also associated with significant morbidity and mortality in immunocompromised patients.

Parainfluenza viral infection is acquired through inoculation of mucous membranes of the respiratory tract with infectious secretions transmitted on fomites or as large, droplet aerosols. Parainfluenza virus can live up to 10 hours on varying surfaces. Laboratory identification is accomplished through the use of direct detection of the parainfluenza using NAATs. There are a variety of monoplex and multiplex panels that are capable of detecting all four types of parainfluenza. Molecular methods have improved sensitivity over serologic or cell culture methods and are particularly useful in rapid diagnosing of infections in immunocompromised patients. Cell culture, using primary or continuous cell lines, followed by confirmatory testing using IFA, DFA, or other methods of antigen detection can also be used but has been replaced by molecular methods in most clinical laboratories.

Mumps is an acute, self-limiting disease characterized by **parotitis** (inflamed salivary gland) accompanied by a high temperature (fever) and fatigue. The mumps virus is transmitted through droplets and contact with contaminated fomites. Humans are the only known reservoir for the virus. Despite the implementation of a trivalent vaccine for measles, mumps, and rubeola in the late 1960s, infections with the mumps virus continue to be on the rise. Research studies have identified new circulating mumps virus strains based on a comparative genomic analysis. This indicates that the current vaccine may not provide adequate protection and may need reformulation. The average incubation period for infection is approximately 16 to 18 days followed by the development of nonspecific respiratory symptoms, slightly elevated temperature and the characteristic enlargement of one or both of the parotid glands. Patients have been reported to develop meningoencephalitis, orchitis, oophoritis, polyarthritis, and pancreatitis as complications following initial infection.

Laboratory diagnosis is generally made by the detection of viral RNA in oral fluid, CSF, saliva, throat, or urine specimens using molecular methods. NAATs are generally more sensitive than viral isolation in culture. There are currently no FDA-cleared molecular assays commercially available for the identification of mumps in clinical samples; however, the CDC has developed and standardized two assays to be used for the identification of the virus. Traditional cell culture can be used, but CPE characterized by rounded and multinucleated giant cells requires 6 to 8 days of incubation and may not appear at all. Rapid shell vial culture can detect pre-CPE within 24 to 48 hours following inoculation. Previous vaccination for the mumps virus may also lower the probability of isolating the virus in cell culture. Therefore, it is important to note that failure to isolate the virus does not rule out infection.

Measles Virus

The measles (rubeola) virus is a pleomorphic, enveloped, nonsegmented single-stranded, negative-sense RNA virus that causes an acute, generalized infection often accompanied by a characteristic rash. The hallmark rash of measles infection is referred to as **Koplik spots,** which are bluish white spots with a red halo located on the buccal or labial mucosa. These spots are found on the inner lip or opposite the lower molars in the mouth. The virus is transmitted from person to person through aerosols and infects the mucosal cells of the respiratory tract.

Measles is one of six classic childhood diseases capable of causing a rash or skin eruption (exanthem). The other diseases that cause an exanthem are scarlet fever (which is caused by a bacterium, group A streptococcus); **rubella** (German measles), referred to as **atypical scarlet fever; erythema infectiosum** (or **fifth disease,** caused by parvovirus B-19); and **roseola** (caused by HHV-6). The illness begins with a cough, coryza, conjunctivitis, and fever. As the symptoms increase over the next several days the Koplik spots develop, before the erythematous rash appears. The rash presents as macules that appear on the forehead or behind the ears, spreading to the trunk, then to the arms and legs. Measles can be fatal as a result of immunosuppression and disseminated CNS complications including encephalomyelitis and subacute sclerosing panencephalitis (SSPE). Infection during pregnancy can result in congenital malformations in the unborn fetus.

Since the introduction of the live attenuated childhood trivalent vaccine against measles, mumps, and rubella (MMR), measles infections are rare in the United States and Europe. However, new outbreaks are becoming more common in the United States because of an increase in the number of unvaccinated individuals. In just the first 4 months of 2019, the CDC reported 465 cases in 19 states, from a virus that was completely eradicated endemically in the year 2000, marked by zero cases over a 12-month period or longer. These viruses continue to circulate and remain a common illness in developing countries. Mortality rates from measles infections can be as high as 20%, as a result of contributing factors such as poor hygiene and malnutrition. These viruses are often brought into the United States by travelers or people from other countries. The potential for an outbreak arises when infected individuals come in contact with unvaccinated individuals, and prompt laboratory investigation of suspect cases is required.

Diagnostic testing for these viruses involves serologic analysis of patient serum for IgM and IgG antibodies and nucleic acid detection. NAAT for viral RNA and nucleic acid sequencing is the only way to distinguish a vaccine reaction from a wild-type viral infection, although IgG avidity assays are also available, which can assist in ruling in a case of measles. For measles cell culture, the specimens of choice are respiratory, oropharynx, conjunctiva, or blood specimens. These viruses are also shed in the urine; therefore, urine specimens can be examined for their presence.

Parvoviridae

Parvoviruses (the Latin term *parvus* means "small") have a wide distribution among warm-blooded animals. Viruses that only cause disease in animals are referred to as **epizootic**. Parvoviruses are small (~22 nm) nonenveloped, icosahedral, linear, single-stranded DNA viruses. At least five different parvoviruses are known to infect humans, with parvovirus B19 being the best characterized. The additional viruses that infect humans include the human bocaviruses, Parv4, human bufavirus, and nonpathogenic adeno-associated virus. Parvovirus B19 is transmitted by close contact through respiratory droplets. The replication of parvovirus B19 in human cells is largely restricted to erythroid progenitor cells, adult bone marrow, and fetal liver cells (the site of erythropoiesis during fetal development). Important diseases associated with parvovirus B-19 infection are fifth disease (the fifth of the childhood exanthems), aplastic crisis in patients with underlying hemoglobinopathies, and fetal infection (hydrops fetalis) resulting from transplacental inoculation. Parvovirus causes a biphasic illness in humans. The first phase, marked by fever, malaise, myalgia, and chills, corresponds to peak levels of virus and destruction of erythroblasts. This phase, when mild, may be overlooked or considered a nonspecific viral disease. The second phase involves rash and arthralgia, which occur after the virus has disappeared but at a time when parvovirus-specific antibody can be detected. This is consistent with the appearance of the rash caused by immune complex deposition in the capillaries of the skin. IgM antibodies appear within 7 days after infection, followed by IgG at approximately 14 days.

Laboratory diagnosis is accomplished using NAAT for the detection of B19 DNA in clinical samples. Molecular methods are extremely sensitive. B19 DNA is easily identified and can be detected months even years following the patient's complete recovery. This necessitates the use of quantitative PCR to distinguish recent or current infection from past infections with the virus. Parvovirus B19 cannot be propagated in traditional cell culture, because the virus can only be grown in erythroid progenitor cells. Therefore, cell culture has not been used for viral propagation outside of the research laboratory. Parvovirus-specific IgM or virus-specific IgG antibody testing with paired acute and convalescent sera can be helpful in the diagnosis of infection. Immunoassays are generally sensitive and specific, and a variety of commercial assays are available.

Picornaviridae

Picornaviruses are small (~30 nm; from the Italian word *piccolo,* meaning "small"), nonenveloped, single-stranded positive-sense RNA viruses. They are among the simplest of the RNA viruses, with a highly structured capsid that has limited surface elaboration. This family of viruses includes the enteroviruses, RVs, parechovirus and cardioviruses, and HAV.

Enteroviruses, Parechoviruses, and Polioviruses

Enterovirus infections are among the most common human viral infections, and although these infections often are mild, the viruses also can cause serious disease. Enteroviruses are responsible for a variety of diseases and conditions, including aseptic meningitis, paralytic poliomyelitis, and encephalitis, in addition to respiratory illness, myocarditis, and pericarditis. Enteroviruses are the most common cause of **aseptic meningitis,** an inflammation of the brain parenchyma, and have been isolated from more than 40% of patients with this disease.

Before the development of the polio vaccine, the polio enterovirus was responsible for paralytic poliomyelitis around the world.

The enteroviruses originally were divided into poliovirus, coxsackie virus, and echovirus groups based on similarity of characteristics in cell culture and disease in humans. Classification based on these criteria resulted in the definition of 67 serogroups of enterovirus. Genetic diversity among these viruses, recognized through the application of modern molecular techniques, dictates that newly characterized strains be given enterovirus-type designations rather than serotype status in one of the three original groups. The molecular and serotype designations provide an improved classification system because of the previously poor disease- and phenotype-based classification system. Human enteroviruses have now been reclassified into seven species, human enteroviruses A to D and RVs A to C. The echoviruses are genetically different from the other enteroviruses and have been renamed HPeV1 and HPeV2. The parechovirus is now classified into two species, PeV A and PeV B. Additional recombinant viruses are continuing to be identified using next generation sequencing.

The enteroviruses and parechoviruses are found worldwide and are transmitted by the respiratory and fecal-oral routes. Therefore, the primary site for viral infection is the respiratory epithelium or the gastrointestinal tract. The five most common viruses associated with endemic infection include enteroviruses type E9, E13, E30, and CVB5 and account for more than 48% of reported cases. Only 3.3% of enterovirus infections have been associated with death. Most infections with both enteroviruses and parechoviruses are asymptomatic. Both viruses also cause a mild viral syndrome that manifests as an acute nonspecific febrile illness with or without a rash. The most serious condition associated with infection is aseptic meningitis. The enteroviruses cause more than 80% of the cases of aseptic meningitis in the United States. HPeV3 has also been identified in association with aseptic meningitis and neonatal sepsis. Systemic disease can cause an infection in any organ system. Poliomyelitis, inflammatory damage to the anterior horn cells of the spinal cord, was traditionally associated with polio virus (PV). However, acute flaccid myelitis (AFM), associated with PV infection, is now more commonly identified in infections with nonpolio enteroviruses (NPEVs), PeVs and circulating vaccine-derived polio viruses (cVDPVs). These cVDPVs are derived from the previous live vaccine (Oral Sabin) used to prevent polio, which have regained their ability to cause poliomyelitis. Several NPEVs are also known to cause AFM. Neonatal systemic disease is associated with EV and PeV acquired *in utero*, perinatally or postnatally within 2 weeks. Finally, respiratory syndromes including pneumonia, bronchiolitis, and lower respiratory disease may be associated with enteroviral infections in young children and infants.

Specimens for the diagnosis of enteroviral infections depend on the clinical signs and symptoms present. Specimens of choice for detecting enterovirus are stool specimens or rectal swabs, throat swabs or nasopharyngeal washings, and CSF. For cases of acute hyperemia conjunctivitis, conjunctival swabs or tears can be used. Serum or plasma may also be used in cases of aseptic meningitis or neonatal sepsis.

NAAT are the preferred method for the diagnosis and identification of EV and PeV. Although both can be readily grown in cell culture and produce a characteristic CPE of visible cell rounding and shrinking, as well as refractility and cell degeneration, the technique has little clinical value due the lengthy incubation times of 10 to 21 days for viral isolation. Molecular methods for the identification of these viruses are sensitive, specific, rapid, and clinically useful for decreasing length of stay during hospitalization. Prior to being tested by nucleic acid–based methods, viral RNA must be extracted to eliminate RNases in the sample and degradation of the viral RNA. Both monoplex and multiplex molecular platforms are commercially available and FDA-cleared for the identification of both EV and PeV.

Serologic testing for the presence of IgM, IgA, or IgM antibodies with ELISA can be used for suspect cases of enterovirus infection, including myocarditis and congenital infections in pregnant women, as well as an epidemiologic tool in enterovirus outbreaks.

Rhinovirus

RV is the cause of the common cold. Similar to other members of the *Picornaviridae,* RVs are small (20 to 27 nm), nonenveloped, icosahedral single-stranded, positive-sense RNA viruses. RVs have been classified as three separate species, A to C. There are approximately 166 recognized serotypes of RVs. It is also important to note that a previous infection with one serotype of RV does not confer immunity to a subsequent infection with a different serotype.

The virus's name reflects the fact that the primary infection and replication site is the epithelial cells in the nose. RVs are responsible for more than 50% of viral colds and cause more upper respiratory viral infections than any other virus. Although typically mild, RV infections can cause complications such as otitis media and sinusitis and can exacerbate previously existing conditions such as asthma, chronic obstructive pulmonary disease (COPD), and cystic fibrosis, in which the risk of severe lower respiratory disease is significantly increased, and morbidity can result. Considerably more cases of lower respiratory tract disease in adults are caused by RV than was previously known. Infection occurs by person-to-person transmission of infected respiratory secretions. Infection usually occurs through self-inoculation through the eyes or nose and also occurs through contact with infectious aerosols. Symptoms usually begin 2 to 3 days after exposure. The clinical presentation includes a profuse, watery nasal discharge frequently accompanied by symptoms of headache, malaise, sneezing, nasal congestion, sore throat, and cough. Illness generally lasts 10 days to 2 weeks.

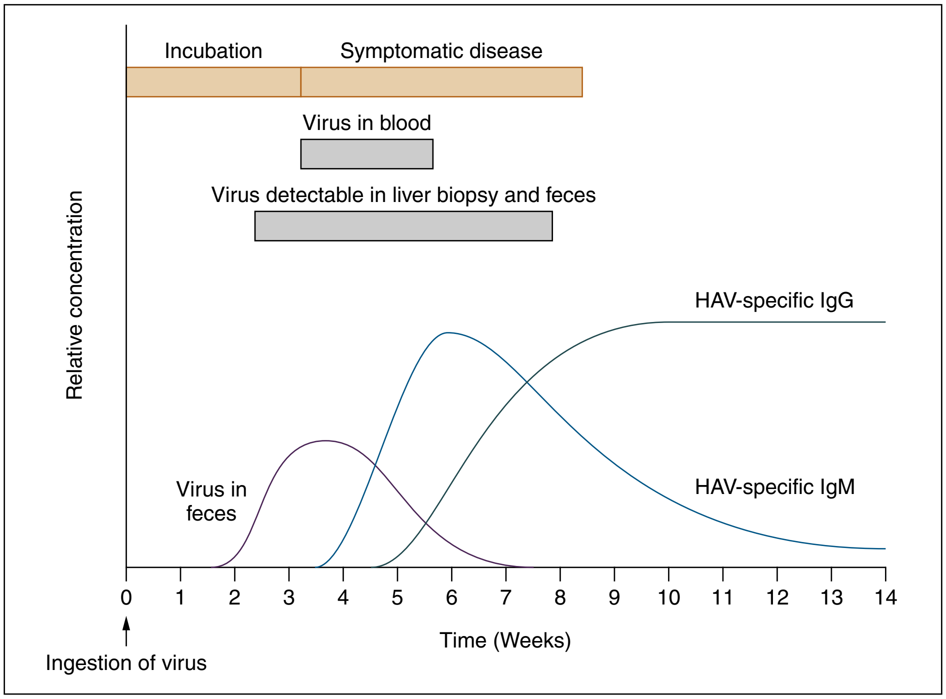
Confirmation of RV infection is rarely required for clinical reasons, because the infection is typically self-limiting. However, the specimen of choice for diagnosis is nasal secretions. NAAT is generally used for detection of RV because of the fast turnaround times and increased sensitivity. As with numerous other viral respiratory pathogens, several commercial monoplex and multiplex assays are available for the detection of RV infections.

Culture can be performed for RV using human cell lines such as MRC-5, human embryonic lung fibroblast strains WI-38, and human embryonic kidney (HEK) cells. CPE usually occurs 1 to 4 days after inoculation. CPE appears as large and small round refractile cells in the fibroblast cell line. The RVs grow best or exclusively at lower temperatures (30°C); therefore, detection in clinical virology laboratories often is unlikely because typical incubation temperatures for viral cell culture are 35°C to 37°C. If required, cell culture conditions should resemble the physiologic environment in the nasal passages, including a pH of 7 and a temperature of 33°C to 35°C. An acid treatment of the clinical sample before culture inoculation can be used to distinguish RV growth from acid-stable enteroviruses. However, this test is not readily available in clinical laboratories because of its complexity and long turnaround time. IFA cannot be used to confirm RV in cell culture, because no mAbs or antigen detection assays are available.

Hepatitis A Virus

HAV, another member of the picornaviruses, causes an infectious nonchronic hepatitis. HAV is usually transmitted through contaminated food or water or household contact with an infected person. Other transmission routes include sharing of contaminated needles (illicit drug use), travel to endemic countries, and homosexual male intercourse. The virus is significantly different from the other picornaviruses based on the liver tissue tropism, high thermal stability, and viral assembly. HAV is a small, icosahedral, single-strand, positive-sense RNA virus that produces two forms of fully infectious viral particles. One form is a small (27 nm), nonenveloped virion that is shed in the feces, and the second is a much larger (50 to 110 nm) virion that is enveloped and circulates in the peripheral bloodstream. Transmission is fecal-oral through the ingestion of contaminated food or water, close contact between infected individuals and less frequently, by anal sexual contact, IV drug use, and contaminated blood products.

NAAT can be used to detect the HAV RNA in blood and stool before clinical symptoms are apparent. Nucleic acid–based testing is useful in establishing early infection. A variety of quantitative and qualitative molecular methods are commercially available for the detection of HAV RNA in clinical samples. HAV is the only hepatitis group of viruses capable of growth in cell culture. A serologic assay to identify the IgM or IgG are available for diagnosis of HAV infection (Fig. 65.5). False-positive HAV IgM results do occur following resolution of the infection and in the



• **Fig. 65.5** Time course of disease and immune response to hepatitis A virus *(HAV)*. (Modified from Murray PR, Kobayashi GS, Pfaller MA, et al., eds. *Medical Microbiology.* 2nd ed. St Louis: Mosby; 1994.)

absence of HAV IgG. A vaccine against this virus for adults and for children older than 2 years of age became available during the 1990s.

Pneumoviridae

The *Pneumoviridae* includes RSV and the human metapneumovirus (HMPVs). RSV is an enveloped, single-stranded, nonsegmented, negative-sense RNA virus. Transmission occurs via respiratory secretions. RSV causes bronchiolitis in young children and is the most significant cause of acute lower respiratory tract infection in children younger than 5 years of age worldwide. The virus is also capable of causing a high rate of morbidity and mortality in adults older than 65 years. According to the CDC, each year in the United States, RSV is responsible for more than 14,000 deaths and approximately 180,000 hospitalizations. The virus contains a surface protein called **F (fusion) protein**. F protein mediates host cell fusion into syncytial cells, which are a hallmark of RSV infection and so named because of the CPE syncytia formation in monolayer cell culture. RSV immune serum prevents severe RSV bronchiolitis during the early months of life in susceptible newborns at risk for RSV disease and those with underlying medical conditions, especially in premature children with underdeveloped lungs.

Diagnostic testing for RSV also is performed using rapid direct antigen testing, nucleic acid detection, and cell culture. Rapid antigen direct tests (RADTs) are simple, waived tests and can be completed within 30 minutes. A variety of RADTs are commercially available; however, the sensitivity is relatively low and can result in false negative results. Multiple monoplex and multiplex platforms for the detection of RSV in respiratory samples are available from commercial manufacturers. The assays also demonstrate an increased sensitivity over RADTs and the rapid diagnosis of infections has improved patient care by reducing the length of stay and duration of antibiotic administration in health care facilities. Cell culture remains the gold standard for the isolation of the virus. Cell culture is not affected by viral mutations that can result in false negatives when using NAAT. However, cell culture requires propagation of cell lines and much higher technical expertise. Several respiratory viruses including parainfluenza virus 3 and the measles virus produce similar CPE. Cell culture requires confirmation with RSV type-specific IF for identification.

HMPV is closely related to RSV. It is a large (150 to 600 nm), enveloped, single stranded, nonsegmented, negative-sense RNA virus. The virus is ubiquitous and infects all age groups. In infections in children, this virus appears to be less common than RSV but more common than parainfluenza virus, making it an important, medically relevant infectious agent. The virus causes bronchiolitis and pneumonia in infants and most likely lower respiratory tract disease in older adults. In infants 6 to 12 months of age, infection with metapneumovirus is likely to show an increase in lower airway involvement. The virus is considered the second or third most common cause of hospitalization for lower airway disease in pediatric patients. Like RSV, metapneumovirus is associated with winter epidemics that vary in severity from year to year. Isolation of metapneumovirus from cell culture is difficult because the virus is very slow to grow and often takes longer than 2 weeks to develop detectable CPE. RADTs are available that are highly specific but have low sensitivity in comparison to NAAT. However, they are frequently used in combination with molecular methods due to their cost, low complexity, and rapid turnaround time. Nucleic acid testing for viral RNA is considered the gold standard for HMPV. There are a variety of FDA-cleared platforms and assays available for the detection of HMPV simultaneously with other respiratory viruses. This is clinically significant in the diagnosis of HMPV because the symptoms are very nonspecific, and it allows the detection of coinfections. Approximately 42% of pediatric HMPV cases were identified to be coinfections with other respiratory viruses. Isolation of the virus using conventional or shell vial culture techniques are of little utility in the clinical laboratory. The virus grows poorly or not at all in most cell lines used for the isolation of respiratory viruses. The CPE is also nondistinctive, requiring specific identification of the virus using mAb (IFA) or nucleic acid (RNA) amplification.

Polyomaviridae

The **polyomaviruses** are small (40 to 45 nm), icosahedral, nonenveloped, circular, double-stranded DNA viruses that have been isolated from many species, including humans. There are 14 different human polyomaviruses (HPyVs) that have been characterized. The first human viruses included the JC (John Cunningham) JCPyV and the BK (renal transplant patient with the initials B.K.) BKPyV viruses, named with the initials of the patients from whom the viruses were first isolated. There are four subtypes of BKPyV, I to IV, and seven subtypes of JCPyV. The subtypes, or genotypes, of the viruses are distributed throughout the world and associated with different human populations and geographic distribution. Infection with these viruses usually occurs during childhood and appears to have little clinical significance. It is believed that the viruses are transmitted through respiratory or oral secretions. Other polyomaviruses, WUPyV, MCPyV, and KIPyV, have been detected in respiratory infections. These viral infections include latent states in the kidney and B lymphocytes and can result in symptomatic reactivation during periods of immune suppression.

Immunocompromised individuals almost always present with the pathologic effects of infections caused by the polyomaviruses. JCPyV virus reactivates, resulting in disease in the CNS; BKPyV virus causes a hemorrhagic cystitis. The MCPyV, which causes Merkel cell carcinoma, is associated with a high percentage of tumors and has also been detected in respiratory specimens. Trichodysplasia spinulosa, a rare skin disease, has been diagnosed in immunocompromised individuals associated with TSPyV infection.

Laboratory diagnosis is generally performed in routine laboratories using NAATs for the detection and quantitation of HPyVs. These assays are very challenging to develop due to the genetic variability of genotypes among these viruses. There are currently no FDA cleared or approved assays available for the identification of polyomaviruses, although some laboratories have developed testing methodologies. The WHO has approved a BKPyV standard produced by the National Institute for Biological Standards and both BKPyV and JCPyV control materials are commercially available from the American Type Culture Collection, Manassas, VA. *In situ* hybridization using BKPyV or JCPyV in conjunction with immunohistochemical staining can be used to identify virus HPyVs in tissue for the diagnosis of clinical disease; however, these methodologies are not available in routine laboratories. Both BKPyV and JCPyV can be isolated in cell culture; however, this method is not used in clinical diagnostic laboratories and is confined to research settings.

Poxviridae

The **poxviruses** are the largest and most complex of all viruses. The virions consist of a double-stranded DNA genome. The virions appear as oval or brick-shaped structures 200 to 450 nm in length. Because of their large size, poxvirus virions may be visualized through a light microscope.

One of the most feared viruses of history, smallpox, is a member of this family. Smallpox played a crucial role in demonstrating the importance of vaccination to protect against disease. Smallpox is known to infect only humans and exists as two distinct subtypes. Variola major, which caused the most severe disease (case fatality rate of 30%), occurred mainly in Asia; variola minor was associated with less severe disease and case fatality rates of 0.1% to 2%. As a result of an intensive vaccination campaign, WHO declared naturally occurring variola virus eradicated in 1980. The variola virus no longer circulates in nature. The virus is feared as a possible biologic weapon, and testing capability for this organism is maintained by hundreds of Laboratory Response Network (LRN) laboratories throughout the nation. All known stocks of the virus are held at two WHO collaborating laboratories: the CDC in Atlanta, Georgia, and the State Center of Virology and Biotechnology (VECTOR) in Koltsovo, Russia. Since the eradication of smallpox in 1980, most vaccination campaigns against this virus have stopped, and most of the world's population lacks any protective immunity against this disease or any related poxviruses.

Besides the smallpox virus, 10 other poxviruses are capable of infecting humans. Except for the smallpox virus and the molluscum contagiosum (MCV) virus, most of these are zoonoses, or infections that result from contact with animals. Fortunately, other than monkeypox (MPXV) and the eradicated smallpox virus (VARV), none of these viruses can sustain human-to-human transmission. The viruses normally are acquired through abrasions of the skin and contact with an infected animal, or in the case of human monkeypox, through the oropharynx, nasopharynx, or abrasions on the skin. Poxvirus replicates in the epidermal cells and causes change in the cellular structure, characterized by the "pocks" on the skin. Poxvirus infection can take one of two courses: it can cause a localized infection at the site of inoculation, with little spread from the original site of inoculation, or it can cause a fulminant, systemic infection that spreads the virus throughout the body, resulting in an increased mortality rate. The second type of infection is associated with variola virus (smallpox) and monkeypox. MPXV is indistinguishable from smallpox infection except that it lacks the same level of mortality and transmissibility. The monkeypox virus is found in the tropical rain forests of Africa. The host reservoir consists of one or more rodent species.

After the individual is exposed to the virus, symptoms of fever and headache occur first, followed by the development of a rash and lymphadenopathy. The rash typically first appears on the face, beginning as **macules** (small, round changes in skin color), progressing to **papules** (slightly elevated with no fluid), to **vesicles** (containing a bubble of fluid), and then **pustules** (containing purulent material consisting of necrotic inflammatory cells). Depending on the severity of the disease, the illness can last 2 to 4 weeks.

Another member of the poxvirus family is the MCV, which causes single or small clusters of lesions. Its only host is humans, and infection occurs either nonsexual, through direct contact or fomites, or sexually, through intimate contact. Usually a self-limiting disease in healthy individuals, molluscum contagiosum can cause a more severe form of disease in immunocompromised patients, resulting in large lesions, especially on the face, neck, scalp, and upper body.

Orf is another member of the poxvirus family and is transmitted from sheep to humans through human direct contact with infected sheep. This virus causes single or multiple nodules, usually on the hands. These nodules may be painful and may be accompanied by symptoms such as low-grade fever and lymph node swelling. The infection usually resolves in 4 to 6 weeks without further complication, although autoinoculation of the eye can have more serious consequences. An orf diagnosis is made through direct examination of the nodule, along with epidemiologic evidence of a recent history of contact with sheep or lambs.

Direct antigen detection for the poxviruses is not routinely performed in diagnostic laboratories. However, a RADT, the Tetracore Orthopox BioThreat assay, which uses a lateral flow system is available to detect the presence of virus in clinical specimens. The CDC has a pan-poxvirus PCR assay that can be used to screen clinical specimens for poxviruses other than avian species. Many national laboratories and LRN laboratories in the United States use NAAT for rapid response to diagnose polyomavirus infections and rule out smallpox.

Reoviridae

The **reoviruses** were first isolated from respiratory and enteric specimens and therefore are referred to as

respiratory-enteric-orphan viruses (reoviruses). The term "orphan" originally was included in the description of the virus as a result of the absence of an associated disease when the viruses were first described. Reoviruses infect most mammalian species and are readily detected in water contaminated with animal feces. Common human pathogens of this family include the rotaviruses and the agent of Colorado tick fever. Rotaviruses are medium-sized (70 nm) nonenveloped, double-stranded, segmented RNA viruses composed of three concentric protein shells: the outer shell, the inner shell, and the core. This triple-layered icosahedral protein capsid gives the virus a wheel-like or "rota" appearance. Based on the proteins present in these shells, rotavirus is further classified into seven distinct groups, A through G; groups A, B, and C cause human disease. Rotavirus is now recognized as the major causative agent of infantile severe gastroenteritis throughout the world. Gastroenteritis caused by rotavirus can occur in children of all ages but is most common in infants from 6 months to 3 years old. The disease is characterized by sudden onset of vomiting, followed by explosive, watery diarrhea and moderate to high fever, often accompanied by dehydration. The severity of the disease often is worse for children in developing countries because of malnutrition and limited or delayed health care. Rotaviruses are transmitted by the fecal-oral route, although airborne transmission has been suspected as the cause of nosocomial infections and outbreaks in nursing homes, hospitals, and day care centers. Rotavirus occurs more frequently in the winter months in temperate climates.

Many methods of laboratory testing are available for the diagnosis of rotavirus. Rotavirus can be detected directly in the stool using ELISA, latex agglutination, IC, RT-PCR, and cell culture. The latex agglutination test and IC platforms offer rapid results with limited laboratory equipment, an advantage in developing countries where resources are limited. A variety of nucleic acid monoplex and multiplex gastroenteritis panels are available for the diagnosis of rotavirus infection. Rotavirus is difficult to cultivate from human specimens. Viral isolation is not normally attempted.

Retroviridae

The retrovirus family *Retroviridae* constitutes a large group of viruses that primarily infect vertebrates. **Retroviruses** are enveloped RNA viruses, and each virion contains two identical copies of single-stranded RNA. The viral nucleic acid strands are surrounded by the structural proteins that form the nucleocapsid and the matrix shell. On the outer surface of the nucleocapsid and matrix protein is the lipid envelope derived from the host cell membrane. Proteins that mediate adsorption and penetration into the host cell membrane are inserted into the viral envelope. Retroviruses are unique, because the virus particle is packaged with the reverse transcriptase enzyme. Reverse transcriptase allows the viral RNA genome to be replicated into DNA and then RNA rather than directly into RNA.

Amino acid sequencing of the reverse transcriptase protein divides the retrovirus family into groups. The human immunodeficiency viruses types 1 and 2 (HIV-1 and HIV-2) are members of this family, as are the human T cell lymphoma viruses types 1 and 2 (HTLV-1 and HTLV-2). HIV-1 (Fig. 65.6) is the more aggressive virus and is responsible for the AIDS pandemic. AIDS is the end stage of a process in which the immune system and its ability to control infections and malignant proliferation is destroyed. The virus has an affinity for the CD4+ surface marker of T lymphocytes. As the number of CD4+ T lymphocytes decreases, the risk and severity of opportunistic infections increases. Some of the most common opportunistic infections associated with HIV infection include disseminated coccidioidomycosis, cryptococcosis, cryptosporidiosis, histoplasmosis, recurrent pneumonia, and pneumocystis pneumonia. Current CDC recommendations for the detection of HIV begins with an initial FDA-approved antigen-antibody combination immunoassay. Reactive specimens with the initial antigen-antibody combination immunoassay should be then tested with an FDA-approved antibody immunoassay that differentiates HIV-1 antibodies from HIV-2 antibodies. Finally, specimens that are reactive on the initial antigen-antibody combination immunoassay and nonreactive or indeterminate on the HIV-1/HIV-2 antibody differentiation immunoassay should be tested with an FDA-approved HIV-1 NAT. For a quick reference guide to this algorithm, see Fig. 65.7. However, the detection of viral nucleic acids using qualitative molecular methods can be useful in diagnosing acute HIV-1 infection and neonatal infections. Diagnosis of HIV infection in babies born to HIV-positive mothers is problematic because of maternal IgG in the baby's blood; therefore, PCR for identification of viral DNA or RNA is recommended. HIV RNA viral load assays are also used to measure the quantity of HIV-1 present in plasma as a prognostic indicator, to monitor treatment and determine infectious status of patients. Clinical management of infected individuals involves the use of highly active antiretroviral therapy (HAART) and depends on the measurement of CD4+ lymphocytes and the viral load. Genome sequencing is used to establish susceptibility to antiviral agents.

HTLVs are fairly large (80 to 100 nm) and enveloped; they contain two positive-sense strand RNA genomes. HTLV-1 is endemic in the Caribbean, Africa, South and Central America, Melanesia, and Japan. However, only a small percentage of people infected (fewer than 4%) develop symptoms and disease. HTLV-1 is associated with two major diseases, adult T-cell leukemia/lymphoma and myelopathy/tropical spastic paresis. The average time from infection to the development of adult T-cell leukemia is approximately 40 years.

Cell-to-cell contact and TAX-induced (HTLV-1 oncoprotein referred to as TAX) clonal expansion of infected cells are the major avenues for viral replication, making detection of the virus difficult. As a result, serologic detection has remained the gold standard for diagnosis. Qualitative

PCR has been used to distinguish HTLV-1 and HTLV-2 infection. Molecular methods are also useful in determining infection status, comparison with serologic results, and determining tissue distribution of the viruses.

Rhabdoviridae

The family *Rhabdoviridae* includes many viruses that result in acute, fatal viral encephalitis. **Rhabdoviruses** infect plants, arthropods, fish, and mammals. The bullet-shaped virion consists of single-stranded RNA with a helical nucleocapsid surrounded by a lipid bilayer envelope. Spikelike projections approximately 10 nm long extend from the surface of the lipid bilayer. The rabies lyssavirus (RABV) is a neurotropic virus that infects all mammals; with very few exceptions, infection terminates in the death of the infected mammal. The RABV is transmitted through the saliva of infected animals, usually by a bite. After inoculation, the virus may initially multiply in the musculoskeletal tissue or invade the peripheral nerves or nerve endings directly. After infection of the nerve cells, the viral genome progresses centripetally transneuronally, through retrograde axoplasmic flow to the CNS. In the CNS it proceeds from first-order neurons to second-order neurons. The neurons are the site of viral replication, mainly in the brain and spinal cord; from there the virus spreads to peripheral nerves and to some nonnervous tissue, including the salivary glands. After a variable incubation period, human disease usually begins with generalized symptoms of malaise, fever, fatigue, anorexia, and headache. Commonly (and characteristically for this disease) symptoms include pain and sometimes tingling at the site of exposure, which can be the first "rabies-specific" symptom. After this prodromal phase, behavioral changes may start to manifest, followed by rapidly progressing neurologic symptoms that lead to coma and death.

Only six cases of survival of a rabies infection have been documented worldwide. These cases include patients who survived without any complications; other patients have experienced significant neurologic impairment. There is no definitive treatment for rabies once clinical signs and symptoms are present. Updated protocol and statistics related to patient treatment and survival are maintained by the Medical College of Wisconsin and can be accessed at https://www.mcw.edu/departments/pediatrics/divisions/infectious-diseases/rabies-registry-website. In the United States today, human fatalities associated with rabies typically occur in people who fail to seek medical assistance, usually because they were unaware of their exposure. This is particularly common with bat bites, which can be as small as a hypodermic needle.

Animal rabies presents similar to human rabies. After the prodromal phase of the disease, a period of increased excitation occurs, with or without aggression. Clinical presentations of rabies often are described as "furious" or "dumb"; the furious type is associated with heightened aggression and agitation, and the dumb type with lethargy and paralysis.

Rabies is diagnosed by postmortem examination of brain tissue using a direct IFA. Specific sections of the brain are examined for the rabies antigen using fluorescent-tagged mAbs and a fluorescent microscope. Prompt, accurate diagnosis of rabies infections in animals is important to ensure the success of post-exposure prophylaxis for human victims of animal bites and injuries. Despite molecular technological advances, NAAT testing is not used in the routine diagnostic laboratory for the detection of RABV. The CDC has developed a RT-PCR assay for the detection of RABV in human antemortem and confirmatory postmortem animal testing procedures.

Togaviridae

The **togaviruses** (*Togaviridae* family) includes rubella virus and the alpha viruses, a large group of mosquito-borne arboviruses. Rubella is found only in the human population and is transmitted through direct contact with nasopharyngeal secretions or by congenital transmission. Rubella, sometimes called the "German measles," is usually a benign disease characterized by fever and rash. Before the trivalent vaccine, MMR, was developed, rubella was an epidemic disease. A risk associated with this disease is exposure and infection of pregnant women. The virus can infect the developing fetus, causing multiple congenital anomalies. Intrauterine infection during the first trimester may result in low birth weight, mental retardation, deafness, congenital heart disease, and neurologic defects. Infection that occurs later in pregnancy may result in splenomegaly or osteomyelitis, among other birth defects. Fetal infection can be prevented through vaccination of all women before pregnancy.

The alphaviruses are medium-sized (60 to 70 nm), enveloped, nonsegmented, positive-sense strand RNA arboviruses. In arbovirus infections, mosquitoes infect a vertebrate host (e.g., birds and rodents); the virus multiplies (amplifies) in this host and is picked up and passed along in subsequent mosquito bites. Humans are infected incidentally and are not amplifiers of the virus; rather, they are dead-end hosts, unable to pass on the virus to other humans or animals. Human disease varies from asymptomatic infection to fatal encephalitis and includes Eastern, Western, and Venezuelan equine encephalitides. Togavirus disease is diagnosed through detection of specific serum IgG and IgM antibodies. A variety of NAATs are available for the detection of some arboviruses; however, many are only available in specialized reference laboratories. Virus isolation is not practical in clinical laboratories.

Prions in Human Disease

Exposure to prions (infectious proteins) can lead to transmissible **spongiform encephalopathies,** a group of uncurable and fatal neurodegenerative disorders of humans and other animals. The most common of the prion diseases in humans, but still relatively rare in incidence (approximately 1 case per million persons per year worldwide), is

Creutzfeldt-Jakob disease (CJD). Even more rare but often publicized in media outlets is **bovine spongiform encephalopathy (BSE),** otherwise known as mad cow disease. Clinically, CJD, BSE, and other spongiform encephalopathies are very diverse in presentation and include behavioral and personality changes, depression, and a range of psychotic symptoms. The molecular bases of BSE and CJD are similar in that, physiologically, all prion diseases are the result of protein misfolding and subsequent propagation of the misfolded protein state within tissues. Aggregates of misfolded proteins form amyloid fibers, ultimately resulting in the formation of tissue plaques. Therefore, similar to viruses but in contrast to bacterial and eukaryotic pathogens, prions are not characterized as living organisms. Most prion disease in humans arises sporadically; some are due to mutations, and others are caused by zoonotic or iatrogenic transmission. However, during disease development, misfolded proteins can induce the misfolding of properly folded proteins within a tissue, which then in turn continue the process of accumulation and dissemination of the aberrant protein. The prion protein aggregates are very stable within the cell, and mass accumulation of the misfolded proteins ultimately leads to cell death and tissue damage.

Prion disease can be diagnosed using a variety of techniques and information, including clinical presentation, family history, brain tissue studies, analysis of CSF, genetic testing, magnetic resonance imaging (MRI), and electroencephalograms. However, autopsy remains the gold standard for definitive diagnosis, disease classification, and determining disease origin.

CASE STUDY 65.1

A 74-year-old male presents to the emergency department with his family. The patient reports having confusion and fever for approximately 2 days. The onset of symptoms was gradual, over several hours, and included frontal headache, fever of greater than 100°F, and myalgias. His wife notes that he has been sleeping a great deal, and she has had trouble waking him to take Tylenol for his headache. Originally the patient believed that this was simply a case of the "flu" and would resolve without a doctor's care.

Upon examination by the physician and during an extensive interview, the patient reveals that he has dysnomia, or difficulty finding the right words to describe his condition. He complains primarily of headache and denies gastrointestinal or respiratory symptoms.

His physical examination results are positive for nuchal rigidity, but no other significant findings are noted.

A lumbar puncture is performed for probable meningitis. The laboratory results are as follows:

Cerebrospinal fluid (CSF): Appears as clear fluid
Red blood cells (RBCs): 112/μL
White blood cells (WBCs): 96/μL, 78% lymphs
Glucose: 78 mg/dL (reference range, 50 to 80 mg/dL)
Serum glucose: 110 mg/dL (reference range, 70 to 140 mg/dL)
Protein: 94 (reference range, 15 to 60 mg/dL)

CSF presentation indicates a potential viral infection because of the WBC count and high percentage of lymphocytes, along with the increased protein content.

Other laboratory results include:

WBC: 13k with normal differential
Hemoglobin (Hgb): 15.8 g/dL
Liver function tests (LFTs): Normal
Creatinine (Cr): 1.4 mg/dL (adult male reference range, 0.8 to 1.4 mg/dL)
Blood urea nitrogen (BUN): 34 mg/dL (reference range, 7 to 10 mg/dL)
Electrolytes: Normal
C-reactive protein (CRP): 7.5 mg (reference range, 1 to 3 mg)
Erythrocyte sedimentation rate (ESR): 25 mm/h (age-normalized reference range, 0 to 20 mm/h)
CRP and ESR consistent with generalized inflammation.
Chest x-ray: Normal
Head computed tomography (CT) scan with and without contrast: Normal

Clinical Summary: The patient has a clinical presentation of meningitis, given the examination finding of nuchal rigidity. This is complicated by confusion and abnormal findings on CSF consistent with a viral infection. Moreover, his confusion is concerning and is an indication for viral encephalitis. MRI of the brain was ordered, and additional studies on the CSF were performed.

Additional laboratory tests included:

Viral culture, serology, and molecular testing
MRI: Brain scan reveals right temporal lobe enhancement.

Questions

1. List some viral agents that may be associated with the patient's symptoms and with probable viral encephalitis.
2. What distinguishing symptoms led the physician to consider a diagnosis of viral encephalitis?
3. Are any notable risk factors associated with this case that typically would alert the physician to a viral infection?

Chapter Review

1. Which family of viruses produces one of the most lethal hemorrhagic fevers?
   - **a.** *Bunyaviridae*
   - **b.** *Filoviridae*
   - **c.** *Flaviviridae*
   - **d.** *Arenaviridae*
2. A pulmonary syndrome, referred to as hanta pulmonary syndrome, that often results in death is carried in the excreta of:
   - **a.** Bats
   - **b.** Cats
   - **c.** Mice
   - **d.** Birds
3. The type of influenza A virus most often associated with greatest human morbidity and mortality is:
   - **a.** Influenza A 2009 pdm H1N1
   - **b.** Influenza A seasonal H1N1
   - **c.** Influenza A seasonal H3N2
   - **d.** Influenza A H1N2
4. The three respiratory agents most often responsible for causing croup in pediatric patients are:
   - **a.** Parainfluenza, RSV, and RV
   - **b.** Influenza A, RSV, and parainfluenza 3
   - **c.** CoV, RSV, and RV
   - **d.** Parainfluenza, RSV, and metapneumovirus
5. The filovirus that has a characteristic shepherd's hook morphology when viewed by electron microscopy is:
   - **a.** Ebola Zaire virus
   - **b.** Ebola Reston virus
   - **c.** Ebola Sudan virus
   - **d.** Marburg virus
6. Which of the following factors does not contribute to the rapid spread and transmission of noroviruses?
   - **a.** Transmission by the fecal-oral route
   - **b.** Nucleic acid segmented genome
   - **c.** Low infectious dose required for infection
   - **d.** High environmental stability of the virus
7. Congenital infections passed from mother to infant often are a cause of severe disease. Which viral agents are responsible for causing congenital infections? (Select all that apply.)
   - **a.** Rubella virus and CMV
   - **b.** Enterovirus and herpes virus
   - **c.** CoV and CMV
   - **d.** EBV and CMV
8. Rotaviruses are most readily detected using which type of laboratory testing?
   - **a.** Cell culture with IFA confirmation
   - **b.** Cell culture using hemadsorption
   - **c.** Nucleic acid testing by PCR or RT-PCR
   - **d.** Serology testing for antigen detection
9. Which of the following viruses are zoonotic?
   - **a.** Hantavirus
   - **b.** Ebola virus
   - **c.** Zika virus
   - **d.** HCV
10. **True or False**

    _____ A virus has a metabolism.

    _____ Exposure to hepatitis A results in a life-long illness.

    _____ Dengue virus is the most prevalent arbovirus in the world.

    _____ Measles infection is often accompanied by a maculopapular rash and swollen parotid glands.

    _____ HIV-2 is the more aggressive of the HIVs and is responsible for AIDS.

    _____ Adenovirus can be readily grown in cell culture and produces a CPE of round, refractile, grapelike cell clusters.

    _____ Norovirus is a significant cause of gastrointestinal infection in infants.

    _____ Another name for the virus causing hanta pulmonary syndrome is SNV.

    _____ HCV chronic infection often results in end-stage liver disease or hepatocellular carcinoma.

    _____ Mosquitoes are the natural reservoir for West Nile virus.

    _____ Enteroviruses are the most common cause of aseptic meningitis.

    _____ Rabies is a neurotrophic virus and affects all mammals.

11. **Matching:** *Match each term with the correct description.*

______ aerosol
______ reservoir
______ host
______ epidemic
______ endemic
______ nosocomial infection
______ epizootic
______ carrier
______ vector
______ zoonotic disease
______ case fatality rate
______ viremia
______ arbovirus
______ prion
______ orf
______ parvovirus B-19
______ EBV

a. number of cases of disease ending in death
b. infective disease passed from animals to humans
c. outbreak of disease in animal population
d. a carrier that transmits an infective agent from one host to another
e. a fine mist containing minute particles
f. viral infection in the blood
g. a person or animal that harbors an infectious agent without showing signs of disease
h. disease that is widespread in a given population
i. a skin infection transmitted to humans by handling sheep
j. an infection acquired at a hospital or health care facility
k. any person, animal, arthropod, plant, soil, or substance in which an infectious agent lives and multiplies
l. arthropod-borne virus
m. one of the childhood exanthems
n. an organism in which a parasite lives and is nourished
o. the occurrence of cases of an illness in a community or region that exceeds the number of cases expected
p. causative agent of infectious mononucleosis and Burkitt lymphoma
q. misfolded protein

12. **Short Answer**

(1) Explain the transmissibility of a vector-borne virus. List some of the viruses transmitted through vectors and the disease associated with the virus.
(2) Human papillomavirus causes genital warts; what is a unique feature of the virus and what strains of this virus are typically responsible for causing cancers?
(3) Explain the difference between antigenic shift and antigenic drift and describe how they affect yearly production of the influenza vaccine.
(4) Explain viral latency; also, list some of the viruses capable of it and the diseases associated with viral reactivation.
(5) Explain how an influenza pandemic can occur. What viral property makes genetic reassortment possible?
(6) What unusual clinical characteristic associated with SARS CoV infection distinguishes this virus from other respiratory viruses?
(7) How did the CoV acquire its name?
(8) Which historic individual studied yellow fever in the tropics? What was the significance of this study?
(9) List the six childhood rashes or exanthemas and the etiologic agents responsible.
(10) Two proteins on the surface of the influenza virus give this virus its unique properties; what are these proteins and what is their function?
(11) What are Koplik spots and for what viral disease are they diagnostic?

66

Antiviral Therapy, Susceptibility Testing, and Prevention

OBJECTIVES

1. Define antiviral resistance and explain what may lead a health care provider to believe that resistance to antiviral therapy is occurring.
2. Define antiviral susceptibility testing and list some of the factors that may vary the end results of testing.
3. Explain the lack of standardization of protocols for antiviral susceptibility testing.
4. Define the criteria that determine whether antiviral susceptibility testing should be performed.
5. Explain the difference between phenotypic and genotypic antiviral susceptibility testing.
6. Name some of the types of phenotypic susceptibility testing and list some of the advantages and disadvantages of this method of susceptibility testing.
7. Describe the methodology of genotypic susceptibility testing and list some of the illnesses for which it is used.
8. List the reasons for drug susceptibility testing for individuals infected with the human immunodeficiency virus (HIV).
9. List the vaccinations used to prevent influenza infection. Also, explain why this vaccine must be reformulated every year and why ongoing surveillance of influenza isolates is crucial to the global vaccination program.
10. Define antigenic shift and antigenic drift as relevant to influenza virus.
11. Name the two classes of antiviral medications used to treat and prevent influenza. Also, list the four antiviral medications that have been approved by the US Food and Drug Administration (FDA) and briefly explain their mode of action and resistance.
12. Define immune prophylaxis. Distinguish disease immunity developed by active immunization and by immune prophylaxis.
13. Describe the process of global eradication of viral diseases. Identify a viral disease that has been globally eradicated, and identify other viral diseases currently considered for eradication.

Antiviral Therapy

Antiviral therapy has expanded over the past several years as a treatment for a number of viral infections. Antiviral agents approved by the US Food and Drug Administration (FDA) are active against one or more viruses (Table 66.1). The viruses that are targeted for treatment include human immunodeficiency virus type 1 and 2 (HIV-1 and HIV-2), human herpes viruses, hepatitis viruses B and C (HBV and HCV), and influenza A and B. Although most of the population is susceptible to such treatments, overuse of these agents has led to the emergence of drug-resistant strains, especially in immunocompromised patients. Drug resistance typically results from mutations that alter the molecular targets of the drug. Ribonucleic acid (RNA) viruses mutate more frequently than deoxyribonucleic acid (DNA) viruses because of the infidelity or error rate associated with RNA polymerases. Resistance has been known to develop against all agents and may be detected *in vitro* by using antiviral susceptibility testing. Testing for viral susceptibility is now considered the standard of practice for the management of viral infections and proper patient care. Virology laboratories are increasingly being asked to perform *in vitro* testing of antiviral agents when a patient's infection fails to respond to antiviral therapy; however, testing for antiviral resistance is not currently available in many clinical settings. This chapter provides an overview of the viral diseases in which antiviral resistance has emerged, the need for *in vitro* susceptibility testing, and the phenotypic and genotypic susceptibility testing methods currently available.

Antiviral Resistance

Antiviral resistance means that a virus has changed in such a way that the antiviral drug is less effective in preventing illness. Antiviral resistance is indicated if a patient is taking an antiviral drug that has been proven *in vitro* to be effective against a virus, but the patient shows no improvement and continues to deteriorate clinically. **Drug resistance** must be distinguished from clinical resistance. With **clinical resistance,** the viral infection fails to respond to the antiviral therapy because of factors other than a change in the virus; such factors may include the patient's immunologic status, the pharmacokinetics of the antiviral drug in the individual patient,

TABLE 66.1 Antiviral Agents

Virus	Mode of Action	Target	Examples of Common Drugs
CMV	Nucleoside analog	Viral DNA	Ganciclovir or valganciclovir
CoV (COVID-19)	Nucleoside analog Nonnucleoside RNA polymerase inhibitor	Viral RNA RNA Polymerase	Remdesivir Favipiravir
HIV[a]	Nucleoside analog Nucleotide reverse transcriptase inhibitor Nonnucleoside analog Protease inhibitor Fusion (entry) inhibitor	Viral DNA Viral DNA Reverse transcriptase Viral protease Virus, host cell membrane	Efavirenz (nonnucleoside analog) Tenofovir disoproxil fumarate (nucleotide reverse transcriptase inhibitor) Emtricitabine (nucleoside analog) Atazanavir (protease inhibitor)
HSV/VZV	Nucleoside analog Pyrophosphate analog	Viral DNA DNA polymerase	Acyclovir (Zovirax) Foscarnet (Foscavir)
Hepatitis B	Nucleoside analog Nucleotide analog	Reverse transcriptase DNA polymerase	Lamivudine Adefovir dipivoxil
Influenza A	Inhibit penetration and uncoating of virus	Host cell membrane	Amantadine, imantadine
Influenza A and B	Prevent release of virus	Neuraminidase inhibitors	Zanamivir, oseltamivir, and peramivir
RSV	Inhibit expression of viral mRNA and protein synthesis	Viral mRNA	Ribavirin
HCV	Inhibit expression of viral mRNA; increase resistance to virus Nucleotide analog	Viral mRNA or neighboring host cells Inhibitor of HCV polymerase	Ribavirin Sofosbuvir
Picornaviruses (enteroviruses and rhinoviruses)	Inhibit attachment and uncoating of virus	Binds to virus	Pleconaril

[a] Many antiretroviral drugs in different mechanistic classes are available to design treatment regimens. See the most recent information for treatment: https://www.hiv.gov/hiv-basics/staying-in-hiv-care/hiv-treatment/hiv-treatment-overview.

CMV, Cytomegalovirus; *DNA,* deoxyribonucleic acid; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *HSV,* herpes simplex virus; *mRNA,* messenger ribonucleic acid; *RSV,* respiratory syncytial virus; *VZV,* varicella-zoster virus.

and, if a combination of drugs is administrated, potential antagonism and interference with the absorption of one or more drugs. Other patient factors that also affect the success of drug therapy include nonadherence to or intolerance to a specific drug and prescriptive errors, such as inappropriate doses or route of administration. In addition, infections in immunocompromised patients may fail to respond to therapy that has proven effective in immunocompetent individuals.

The final result of antiviral susceptibility testing is determined by many variables, and these variables also hinder the standardization of antiviral susceptibility testing. Some of these variables include the following:

- Cell line used to grow the virus
- Inoculum viral titer
- Culture incubation time
- Concentration range of the antiviral drug tested
- Reference strains
- Assay method
- End-point criteria
- Calculation of the end-point
- Interpretation of the end-point

Each of these categories in turn has variables that affect the final results. For example, if the inoculum quantity is too large, a susceptible isolate may appear resistant; if the inoculum quantity is too small, the isolate may appear susceptible. The complexity of all these variables makes it imperative that established control strains also be tested when antiviral susceptibility testing is performed. Controls should include both drug-resistant and drug-susceptible isolates that have been well characterized. Several research laboratories across the nation can provide reference and drug-resistant strains of a virus for susceptibility testing; they include the National Institute of Allergy and Infectious Diseases AIDS Research and Reference Reagent Program (niaid.nih.gov) and the American Type Culture Collection (atcc.org). Pharmaceutical companies may also maintain control strains.

Methods of Antiviral Susceptibility Testing

The purpose of antiviral susceptibility testing is to evaluate new antiviral chemoprophylaxis, to test for cross resistance or cross reactivity to alternate agents, and to determine how frequently drug-resistant viral mutations occur.

The two general types of antiviral susceptibility testing are phenotypic testing and genotypic testing. **Phenotypic susceptibility assays** measure viral replication in the presence of antiviral agents; they measure the inhibitory effect of an antiviral agent on the entire virus population in a clinical isolate. **Genotypic susceptibility assays** use polymerase chain reaction (PCR) to detect genes known to be responsible for resistance, coupled with molecular sequencing to determine whether genome alterations associated with resistance have occurred. These assays use the virus's nucleic acid to determine whether the virus has mutations capable of causing viral drug resistance. Alternately, a combination of the two general types of antiviral susceptibility, known as a **virtual phenotype resistance assay,** may be performed. This assay is a characterization of the patient's virus genotype compared with a database that includes paired genotypic and phenotypic information. This information is then used to estimate the most likely phenotype of the patient's virus. The success of this approach varies with the virus type and antiviral drugs examined.

Each of these types of susceptibility testing has unique properties that can be used to complement each other. Phenotypic assays are better used to assess the combined effect of multiple-resistance mutations on drug susceptibility, but they are labor intensive, are expensive, and have lengthy turnaround times. Genotypic assays have a shorter turnaround time and are less expensive than phenotypic assays, but they can detect only defined viral mutations that may or may not result in a drug-resistant phenotype.

Phenotypic Assays

Phenotypic assays use a variety of end-point measurements to determine whether a virus is inhibited by an antiviral drug or demonstrates drug resistance. Some of these endpoint measurements include a reduction in the number of plaques, inhibition of viral DNA synthesis, a reduction in the yield of a viral structural protein, or a reduction of the enzymatic activity of a functional protein. As mentioned, an advantage of phenotypic assays is that they are much better for assessing the combined effect of multiple-resistance mutations on drug susceptibility. This has been useful for assaying viruses such as HBV, HIV-1, and human cytomegalovirus (HCMV), which acquire resistance mutations in multiple genes. The disadvantages of phenotypic assays are that they are labor intensive, expensive, and require weeks to perform.

Plaque Reduction Assay

The **plaque reduction assay (PRA)** is the standard method of antiviral susceptibility testing against which new methods are compared. CLSI has developed standardized PRA protocols for antiviral susceptibility testing for HSV. This test is based on the principle of inhibition of viral plaque formation in the presence of an antiviral agent. The concentration of antiviral drug that inhibits plaque formation by 50% is the **IC50**; that is, the 50% inhibitory concentration and 50% effective concentration.

Dye Uptake Assay

The **dye uptake (DU) assay** has been used for years in the susceptibility testing of HSV. When the virus is in the presence of an antiviral drug, only cells that are alive and viable take up a vital dye called **neutral red.** After infection with HSV, the relative amount of dye bound to viable cells compared with that bound to uninfected cells determines the extent of the viral lytic activity. The drug concentration that inhibits viral lytic activity by 50% is the IC50. This assay is also used for other herpes viruses, including cytomegalovirus (CMV) and varicella-zoster virus (VZV).

Enzyme Immunoassay

The enzyme immunoassay (EIA) uses spectrophotometric analysis to quantitatively measure the amount of viral activity. The concentration of antiviral agent that reduces the amount of absorbance by 50% compared with the absorbance values of a viral control is the IC50. This method of susceptibility testing has been used for influenza A, HSV, and VZV.

Neuraminidase Inhibition Assay

The **neuraminidase (NA) inhibition assay** is used to detect NA inhibition resistance when the drugs oseltamivir and zanamivir are used to treat influenza A and influenza B infections. Oseltamivir and zanamivir act by inhibiting the influenza viral protein NA. Resistance to these drugs is measured by incubating cultured influenza isolates containing NA with varying concentrations of the drugs. A fluorogenic substrate is then added, allowing the fluorescence to be quantitated by a fluorimeter. The IC50 is calculated by comparing the activity of viral NA to a control reaction that does not use any NA inhibitors.

Recombinant Virus Assays

A **recombinant virus assay (RVA)** monitors the phenotypic behavior of specific genes in the virus genome in the presence of the antiviral drug. One of the first RVA assays measured HIV-1 resistance to protease and reverse transcriptase inhibitors. An artificial genetic construct that includes a vector nucleic acid molecule with a reporter, as well as the patient's gene of interest, is recombined into a **chimeric molecule.** This is then **cotransfected** into a susceptible cell line. The chimeric structure, or **pseudovirus,** can then be tested *in vitro* in the presence of antiviral drugs. The chimeric molecule emits light from the reporter during viral replication. If the virus is susceptible to the antiviral, the light emission will decrease, indicating a potential effective treatment against the viral gene that has been introduced into the recombinant structure.

Genotypic Susceptibility Assays

Genotypic susceptibility assays use PCR to detect genes known to be responsible for resistance, coupled with genetic sequencing to determine whether genome alterations associated with resistance have occurred. Genotypic assays use DNA Sanger sequencing, pyrosequencing, and next-generation sequencing by automated sequencers; PCR amplification and single nucleotide polymorphism (SNP) multiplex assays for allelic discrimination; and *in vitro* reverse hybridization line probe assays (LIPAs). These assays are rapid, because isolation of the virus in culture is not necessary for testing.

The response to an antiviral agent is also measured by quantitative monitoring of the viral load (by means of the nucleic acid concentration) in the patient's blood. Such testing is common in patients infected with HBV, HCV, and CMV. Genotypic assays have been used to identify mutations in the VZV thymidine kinase (TK) and DNA polymerase genes resulting in antiviral resistance. The viral load in genotypic susceptibility assays should diminish significantly after addition of an antiviral agent to which the virus is susceptible. Using molecular testing (e.g., quantitative PCR) to measure the amount of virus in serum is a surrogate test for resistance to antiviral agents. The viral load rises quickly when resistance appears.

Pyrosequencing

DNA sequencing is among the most important testing methods for the study of biologic entities. Pyrosequencing is a sequence-based detection method that allows rapid, accurate quantification of sequence variation. It allows rapid acquisition of short reads (100 to 200 bp) of genomic sequence to identify known mutations. It is based on the technology of detection of released pyrophosphate (PPi) during DNA synthesis. (See Chapter 8 for more information of pyrosequencing.) In a sequence of enzymatic reactions, a polymerase enzyme catalyzes the addition of nucleotides into a nucleic acid chain. A PPi molecule is released and converted to adenosine triphosphate (ATP) by the ATP enzyme sulfurylase. Visible light is produced when a luciferin molecule is oxidized during the luciferase reaction. The visible light or signal strength generated is proportional to the number of nucleotides incorporated into the final product.

Two types of pyrosequencing methods are available: the solid-phase pyrosequencing and liquid-phase pyrosequencing. Solid-phase pyrosequencing involves a three-enzyme system that uses immobilized DNA, and a washing step is performed to remove excess substrate after each nucleotide addition. In liquid-phase pyrosequencing, a fourth nucleotide-degrading enzyme (made from potato) is added. The advantage of the liquid-phase system is that it eliminates the need for solid support and the intermediate washing step, allowing the reaction to be performed in a single tube.

Because of its rapid, accurate quantification of sequence variation, pyrosequencing is an adaptable tool that can be used for a wide range of applications. Automation with pyrosequencing is made possible by the liquid-phase methodology. Pyrosequencing signals are quantitative, which allows many people to be screened through examination of the allelic frequency in a population. This technique also is used taxonomically to group different organisms into strains or subtypes, and it can be applied to bacteria, yeasts, and viruses. The technique can be applied to the resequencing of PCR-amplified disease genes for mutation screening. It also is used to screen clinical isolates for the genes that confer resistance to antiviral therapy, such as for analysis of influenza specimens for the adamantine resistance mutation. There are no FDA cleared or approved pyrosequencing methods for use in antiviral susceptibility testing.

Next Generation Sequencing

Next generation sequencing platforms are increasingly becoming used for the diagnosis of emerging viral agents, molecular epidemiology, and drug resistance testing. These methods depend on the development of large databases of information that include the drug-resistant mutations and their association with viral phenotype, treatment, and clinical outcomes. This process will require continued development of resistance databases and automation. See Chapter 8 for more information on whole-genome next generation sequencing (WG-NGS).

Human Immunodeficiency Virus

Patients infected with HIV commonly develop resistance to the antiretroviral drugs, which often results in treatment failure. Genotypic testing is recommended for baseline screening of all newly diagnosed patients. Testing for antiretroviral resistance is crucial to the assessment of a regimen of drugs intended to suppress HIV replication and to test for cross resistance to alternative antiretroviral drugs. The US Department of Health and Human Services and a European panel of experts have developed guidelines and established protocols to monitor patients with acute and chronic HIV infection. Susceptibility testing should proceed as follows:

1. Before the initiation of therapy
2. When antiretroviral regimens are changed in cases of treatment failure
3. When suboptimal viral load reduction is seen after beginning or changing therapy

A single FDA-cleared assay is also available for HIV-1 genotyping, the ViroSeq HIV-1 system (Abbott Diagnostics, Abbott Park, IL). This method uses a PCR amplification followed by Sanger sequencing of the protease and reverse transcription gene. A variety of specialized and large reference laboratories have developed laboratory developed tests (LDTs) for the detection of antiviral mutations for various drugs used to treat HIV.

Genotypic susceptibility testing has become a routine component of the management of patients infected with HIV. Genotypic assays for mutations that confer resistance are useful because of their rapid turnaround time.

Influenza

Currently, two main approaches are used in health care to control the spread of influenza: vaccination and the use of antiviral drugs. The influenza virus has the unique capability of being able to change its antigenic makeup; this mechanism, known as antigenic drift, occurs with all three types of influenza virus (A, B, and C). Influenza A shows the greatest rate of antigenic change. Antigenic drift is caused by sequential point mutations in the hemagglutination (HA) or NA genes that arise during viral ribonucleoprotein (RNP) replication and immune selection, giving rise to new strains; this gives the virus the ability to reinfect "nonimmune" susceptible hosts each season. Another phenomenon, antigenic shift, is manifested only by the influenza A virus. It involves complete reassortment of the segmented viral genome during a coinfection with a nonhuman animal, which results in major antigenic change and periodic worldwide outbreaks (pandemics) of a never-before circulated type of influenza A virus. Influenza B undergoes antigenic change very slowly.

Antigenic drift requires the reformulation of the influenza vaccine each year to ensure maximum efficacy against the currently circulating strains of influenza A and influenza B. This is accomplished by global surveillance of the yearly influenza epidemics to evaluate the strains that are circulating and provide early detection of viruses that may have pandemic potential. The World Health Organization (WHO) coordinates an influenza surveillance program in more than 80 countries. In the United States, the surveillance program established by the Centers for Disease Control and Prevention (CDC) includes monitoring of pneumonia and influenza deaths above a calculated "**epidemic threshold.**" It also includes tallying pediatric deaths, assessment of weekly virology data, and typing of influenza virus isolates submitted by reference laboratories. This extensive surveillance system provides the data for determining and predicting the influenza strains likely to be circulating in the upcoming winter. Vaccine components are chosen annually by WHO based on the analysis and typing of these strains. The summer months are used to manufacture the vaccine so that it is ready for distribution to health care providers in early autumn. In the United States, the vaccine is prepared from viruses grown in embryonated chicken eggs. The vaccine may be a trivalent vaccine containing two influenza A strains with the newest HA and NA surface antigens and a current type B strain or a quadrivalent vaccine containing antigens to two influenza A and two influenza B strains.

Several types of vaccine are used to prevent influenza infection: the inactivated influenza vaccine (IIV3), the live attenuated influenza virus vaccine (LAIV), and the recombinant hemagglutinin vaccine (RIV). The IIV3 is a noninfectious vaccine (Afluria) administered intramuscularly for individuals 5 years and older or using a high-pressure jet injector for individuals 18 years through 64 years of age. The IIV3 vaccines may be trivalent containing influenza A (H1NA), A (H3N2), and B or quadrivalent containing influenza B viruses from two lineages (B/Victoria and B/Yamagata). A high dose flu vaccine referred to as Fluzone-High is a trivalent vaccine that contains four times more antigen than the standard inactivated flu vaccine. Fluzone-High dose is specifically licensed for patients 65 years of age and older. An additional trivalent inactivated virus vaccine, Fluad, is also available for patients 65 years of age and older. Fluad contains the adjuvant MF59, which increases the patient's immune response to the vaccine providing improved protection from influenza infection. There are at least four quadrivalent flu vaccines available that are either egg based or cell based on recombinant vaccines. There are many vaccine options available; however, everyone that is 6 months of age or older should receive an annual influenza vaccine.

The LAIV contains live whole infectious virus. The LAIV causes shedding of the virus that is detectable in rapid antigen assays for about a week. The LAIV is also quadrivalent and contains the same strains as the IIV quadrivalent vaccine. The RIV contains 45 μg of baculovirus-expressed, recombinant hemagglutinin for A (H1NA) and A (H3N2) and an influenza B strain. The strains included in vaccines are reviewed twice annually by the WHO.

Two classes of antiviral drugs, the adamantanes (M2 protein inhibitors) and the NA inhibitors, currently are used to treat influenza infections. The adamantanes, which include the drugs amantadine and rimantadine, were the first class of antiviral, antiinfluenza drugs developed. The drugs function by blocking the virion M2 ion channel, which prevents the virus from uncoating. This class of drugs is effective only at treating cases of influenza A; it has never had any effect on influenza B infections. The NA inhibitors include the drugs zanamivir (Relenza), oseltamivir (Tamiflu), and peramivir. Peramivir was approved for use in 2014; however, it is only available as an intravenous injection and is given in a single dose for uncomplicated influenza. These drugs inhibit the viral protein NA, which prevents release of the virus from infected cells. The NA inhibitors are used to treat both influenza A and influenza B infections, although oseltamivir has been reported to have lower efficacy against influenza B. Both classes of drugs have proven to be most effective when administrated within 48 hours of symptoms. The drugs shorten the duration of the infection and reduce complications.

The need for effective influenza antiviral susceptibility surveillance has increased around the world, and its importance is validated by the emergence of universal resistance to the adamantine antiviral therapy for influenza A (H3N2). Samples of viruses collected from around the United States and worldwide are studied to determine whether they are resistant to any of the four influenza antiviral drugs approved by the FDA. The CDC, in collaboration with state public health departments and WHO, conduct ongoing surveillance and perform testing of influenza viruses to monitor the development of antiviral resistance. The number of domestic and global surveillance sites are being increased, and the data from this surveillance are used to make public health policy recommendations on the use of antiviral medications. The CDC is constantly improving the methods for rapid detection and monitoring antiviral resistance. Several LDTs including real-time assays, high-resolution melt RT-PCR, SNP analysis using capillary electrophoresis, and real-time allelic discrimination assays have been developed for influenza susceptibility testing. Sanger and pyrosequencing assays are also used to identify resistance mutations in the NA gene. Laboratory methods for testing are constantly being improved, and the number of laboratories capable of antiviral resistance testing is increasing.

Antiviral resistance to the M2 protein inhibitors develops in about 30% of patients following a few days of therapy. Natural resistance has also emerged in influenza A H3N2 and H1N1. Because of the high prevalence of drug-resistant strains, these antivirals are no longer recommended for treatment in the United States. Resistance mutations to the neuraminidase inhibitors depend on the influenza type (A or B) and subtype (N1 or N2). This requires ongoing genotypic and phenotypic surveillance and susceptibility testing. Genotypic assays are generally used for clinical management and surveillance, whereas enzymatic assays are used for surveillance and characterizing novel NA variants.

TABLE 66.2 Examples of Vaccines for Preventing Viral Diseases

Disease	Type of Vaccine
Yellow fever	Attenuated-live
Polio virus (PV)	Inactivated
Measles	Attenuated-live
Mumps	Attenuated-live
Rubella	Attenuated-live
Hepatitis B (HBV)	Inactivated and recombinant
Influenza	Attenuated-live, inactivated, and recombinant
Smallpox virus (VARV)	Attenuated-live
Chickenpox (VZV)	Attenuated-live
Hepatitis A virus (HAV)	Inactivated
Human papilloma virus (HPV)	Recombinant
Rabies virus (RABV)	Inactivated
Rotavirus (RV)	Attenuated-live

VARV, Variola virus; *VZV,* varicella-zoster virus.

Prevention of Other Viral Infections

Vaccination

Control of many viral diseases has been accomplished by vaccination. Since Jenner developed the first vaccine against smallpox 200 years ago, attenuated-live or inactivated-dead viral vaccines have been used successively to prevent yellow fever, poliomyelitis, measles, mumps, rubella, hepatitis B, and influenza (Table 66.2). Smallpox was eliminated in 1977 by an effective vaccination program. Additional vaccines continue to appear. New smallpox vaccines with fewer side effects are being developed to prevent outbreaks in the event of bioterrorism. A live-attenuated varicella (chickenpox) vaccine is now recommended for all children, and an inactivated hepatitis A vaccine is available for travelers and others entering areas of higher endemicity. Rotavirus vaccines are approved by the FDA and are now available. Recombinant vaccines are also available for the prevention of HPV infection.

Immune Prophylaxis and Therapy

Immune prophylaxis is used to prevent serious viral infection in patients who are immunocompromised or functionally compromised. Instead of actively immunizing an individual with an antiviral vaccine, limited protection can be conferred by intramuscular inoculation of human immunoglobulin. Pooled human immunoglobulin contains antibody against all common viruses. Specific high-titered immunoglobulin can be collected from patients recovering from a specific infection to ensure maximum antibody levels. Immune prophylaxis should be considered an emergency procedure. Table 66.3 lists immune prophylaxis available for viral infections.

Passive immunoprophylaxis of respiratory syncytial virus (RSV) infection in infants younger than 2 years who have underlying lung disease resulting from premature birth or congenital heart disease is particularly effective at preventing life-threatening bronchiolitis and pneumonia in this patient group. The drug, palivizumab (Synagis), is a manufactured antibody to RSV. It is used in certain infants and young children to prevent RSV infections of the bronchioles and lungs; it cannot be used to treat a child that already is symptomatic because of an RSV infection.

Passive immunization occasionally is effective as therapy for viral infection (Table 66.3). Therapy with immune serum for some hemorrhagic fevers, such as Lassa fever, has also been successful in reducing mortality associated with the disease.

Eradication

Global eradication of a viral disease has occurred only with smallpox. Factors that result in eradication of any viral

TABLE 66.3 Immune Prophylaxis or Therapy for Viral Diseases

Disease	Circumstances of Use
Prophylaxis	
Hepatitis A virus (HAV)	Traveler to developing country
Hepatitis B virus (HBV)	Newborns of infected mothers or unimmunized laboratory worker after needlestick
Rabies virus (RABV)	After bite from potentially rabid animal
Measles	Unimmunized close contact with infected individual
Varicella-zoster virus (VZV)	Newborns of infected mothers at time of delivery
Respiratory	Infants younger than 2 years of age with underlying lung syncytial disease virus
Therapy	
CoV (COVID-19)	Immunomodulators such as tocilizumab an IL-6 inhibitor are used reduce potential cytokine storms and other immune related damage in severe to critical cases.
Lassa fever	During disease to reduce severity

disease include no animal reservoir, a lack of recurrent infectivity, one or few stable serotypes, and an effective vaccine. Viral diseases currently considered candidates for eradication include measles and poliomyelitis. Poliomyelitis has been known and feared by humans for thousands of years. Infection with the poliovirus causes an acute flaccid paralysis that can affect the ability to breathe. The disease was often seen in children. In the mid-1950s, Jonas Salk developed the first polio vaccine from dead virus, and in 1960, Sabin developed an oral polio vaccine using a live-attenuated virus. These developments allowed the United States to launch a massive vaccination program against polio, and the last case of indigenous polio was reported in the United States in 1979 (other reports of polio cases were a result of vaccination or occurred in individuals who had emigrated from other countries).

In 1988, WHO resolved to eradicate acute paralytic poliomyelitis from the rest of the world and staged a massive vaccination campaign to accomplish this. WHO has continued this effort with many collaborating agencies as the Polio Global Eradication Initiative. Detailed information and updates can be located at http://polioeradication.org/polio-today/. The strategies to eradicate the disease include surveillance of acute flaccid paralysis, routine vaccination with the oral polio vaccine, and supplementary immunization activities.

CASE STUDY 66.1

A 25-year-old male named Joe sought medical attention from his personal physician. Joe reported that he recently found out his male partner, with whom he was living, had visited a gay bar a month before and spent the night with someone he met there. The partner told of his sorrow over the unfaithful episode and mentioned that he had been feeling weak and exhausted for the last few days: he had been having flulike symptoms, specifically fever, headache, and rash, but refused to seek medical attention. Joe reported to his physician that he himself was now having similar symptoms, but unlike his partner, Joe decided to talk with his physician. Several laboratory tests were ordered, including a PCR for HIV, which came back positive. The physician prescribed Joe a combination antiretroviral therapy (ART) treatment plan consisting of three HIV medicines from at least two different drug classes—specifically efavirenz (nonnucleoside reverse transcriptase inhibitor), emtricitabine (nucleoside reverse transcriptase inhibitor), and tenofovir disoproxil fumarate (nucleoside reverse transcriptase inhibitor) in the form of Atripla (brand name) as a preliminary treatment plan.

1. Is HIV drug-resistance testing recommended, especially because Joe is a newly identified HIV patient?
2. What is involved in HIV genotypic testing?
3. Besides antiretroviral-naïve patients, what other patient populations should have HIV genotype testing?
4. What factors, other than changes in the virus, influence clinical resistance that can affect the success or failure of the drug regimen?

Case study was developed based upon information at the AIDSinfo website (https://aidsinfo.nih.gov). Accessed July 30, 2019.

Chapter Review

1. Antiviral susceptibility testing is used for all the following reasons *except:*
- **a.** To evaluate new antiviral chemoprophylaxis
- **b.** To define viral recombinant proteins for replacement of the whole virus antigen
- **c.** To test for cross reactivity to alternate drugs
- **d.** To test for the frequency of drug-resistant viral mutations

2. Genotypic susceptibility testing involves all the following *except:*
- **a.** Serum procalcitonin (PCT) detects genes known to be responsible for resistance
- **b.** Genetic sequencing to determine whether genome alterations have occurred
- **c.** SNP multiplex assays
- **d.** *In vitro* reverse hybridization line probe assays

3. Which of the following phenotypic antiviral susceptibility tests is the method against which all other types of susceptibility tests are compared?
- **a.** NA inhibition assay
- **b.** DNA hybridization assay
- **c.** DU assay
- **d.** Plaque reduction assay

4. IC50 stands for which of the following?
- **a.** The concentration of antiviral drug that inhibits viral plaque formation by 50%
- **b.** The 50% inhibitory concentration
- **c.** The 50% effective concentration
- **d.** All the above

5. Antiviral resistance mutations must be monitored annually using what methods?
- **a.** Genotypic surveillance
- **b.** Phenotypic surveillance
- **c.** Antiviral susceptibility testing
- **d.** All the above are required annually

6. Influenza A has the unique capability to alter its genetic composition. Which of the following genetic changes is the reason for the annual reformulation of the influenza vaccine?
- **a.** Antigenic drift
- **b.** Antigenic shift
- **c.** Interspecies transmission
- **d.** Gene reassortment during mixed infection

7. True or False

_____ Antiviral susceptibility testing is governed by several standards established by the Clinical and Laboratory Standards Institute.

_____ Influenza B infection is effectively treated with drugs from the adamantane class of antiviral medications.

_____ Drug resistance must be distinguished from clinical resistance when the success of an antiviral drug regimen is evaluated.

_____ Genotypic susceptibility assays are better used to assess the combined effect of multiple-resistance mutations on drug susceptibility.

_____ The trivalent inactivated influenza vaccine (TIV) is a noninfectious vaccine administered intranasally.

_____ Each of the variables of a phenotypic susceptibility test (e.g., type of cell culture used, viral inoculums titer, incubation time, and so on) affect the final test result.

8. **Matching:** *Match each term with the correct description.*

_____ pyrosequencing
_____ eradication
_____ phenotypic susceptibility assays
_____ genotypic susceptibility assays
_____ antigenic shift
_____ antigenic drift
_____ prophylaxis
_____ plaque reduction assay
_____ DU assay
_____ EIA
_____ NA inhibition assay

a. HSV susceptibility testing; viable cells take up dye, nonviable cells do not
b. complete reassortment of the segmented viral genome
c. uses spectrophotometry to quantitatively measure the amount of viral lytic activity
d. standard method of susceptibility testing to which new methods are compared
e. sequencing method based on the detection of released pyrophosphate during DNA synthesis
f. drug treatment for at risk populations to prevent infection
g. uses end-point measurements to determine viral inhibition in the presence of antiviral drugs
h. sequential point mutations in the HA or NA genes that give rise to new strains
i. tests for genetic material that confer the mutations associated with resistance
j. allows fluorescence to be quantitated by a fluorimeter
k. attempts at eliminating a viral agent from the human population

9. **Short Answer**

(1) Give a brief description of the two types of antiviral susceptibility testing, including the advantages and disadvantages of each type.
(2) Explain the phenomena of antigenic shift and antigenic drift. What virus is responsible for these phenomena, and what are the major consequences of these events?
(3) Explain the importance of susceptibility testing for individuals infected with HIV.
(4) Describe the genotypic assay of pyrosequencing. How has this assay benefitted antiviral susceptibility testing?

67

Bloodstream Infections

OBJECTIVES

1. Identify and describe some of the medical consequences that occur when the bloodstream is infected by microorganisms.
2. Name the most common causes of bacterial bloodstream infection and explain the routes of transmission and source of infection.
3. Define the following bloodstream infections: bacteremia, fungemia, and septicemia.
4. List the most common fungi associated with bloodstream infections and the population of patients most often affected by this type of infection.
5. Explain what causes mortality in most cases of parasitic bloodborne infections.
6. Differentiate between intravascular and extravascular bloodstream infections.
7. Define continuous bacteremia and provide an example.
8. Describe the development of infective endocarditis, including the contributing factors and the microorganisms that are the primary cause for the condition.
9. Define mycotic aneurysms and suppurative thrombophlebitis and describe the causes for these conditions.
10. Explain the pathogenic features of *Staphylococcus epidermidis* that make it uniquely suited for causing catheter-related infections.
11. Explain the importance of collection parameters associated with blood cultures for suspected cases of bloodstream infections, including collection time, the number of cultures, and the volume of blood required.
12. List and briefly describe some of the blood culture systems available to the microbiologist, including the self-contained systems, the lysis centrifugation systems, and instrument-based systems.
13. List some of the most common causes of bloodstream infection associated with the blood cultures from HIV-infected patients.
14. Define the acronym HACEK and describe the type of bloodborne infections these organisms are most often associated with.
15. Outline the guidelines used to determine whether agents isolated from blood cultures are true pathogens or probable contaminants.

Invasion of the bloodstream by microorganisms constitutes one of the most serious situations in infectious disease. Microorganisms present in the circulating blood—whether continuously, intermittently, or transiently—are a threat to every organ in the body. The suffix –**emia** is derived from the Greek word meaning "blood" and refers to the presence of a substance in the blood; **bacteremia** refers to the presence of bacteria in the blood, **viremia** refers to the presence of a virus in the bloodstream, **parasitemia** refers to the presence of a parasite in the blood (Chapters 48, 52, and 57), and **fungemia** refers to the presence of fungi in the bloodstream. **Sepsis** or **septicemia** therefore indicates organisms are present in the blood, producing an infection and reproducing within the bloodstream. Invasion of the bloodstream resulting from any organism can have serious immediate consequences, including shock, multiple organ failure, **disseminated intravascular coagulation (DIC),** and death. According to the Centers for Disease Control and Prevention (CDC), the incidence of sepsis or bloodstream infections has nearly doubled in the past decade. It is one of the leading causes of death in the United States and one of the most expensive conditions to treat in a hospital, accounting for approximately 20% of all intensive care unit (ICU) admissions and the leading cause of ICU noncardiac mortality. Timely detection and identification of bloodborne pathogens are two of the most important functions of the microbiology laboratory. This includes traditional culture-based methods as described previously in Chapter 7 as well as newer rapid detection methods such as nucleic acid–based testing (Chapter 8) or chemotaxonomic methods such as matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS), also included in Chapter 7. To combat the rising incidence of sepsis, algorithms for diagnosis and treatment of sepsis are being instituted to reduce mortality. These algorithms include microbiologic testing, clinical chemistry (lactate, procalcitonin, and other biochemical markers), delivering fluids for hydration, and initiating rapid treatment with broad spectrum antibiotics.

General Considerations

The successful recovery of microorganisms from blood by the laboratory depends on many, often complex, factors: the type of sepsis, the specimen collection method, the blood volume, the number and timing of blood cultures and the use of supportive diagnostic information, the interpretation of results, and the type of patient population being served by the laboratory. All these parameters must be considered in the development of the diagnostic protocol within the laboratory to maximize the detection and recovery of microorganisms and ensure quality patient care. Bloodstream infections dramatically increase health care costs and mortality. The definition and delineation of the clinical syndromes associated with bloodstream infections have been standardized by the American College of Chest Physicians and the Society for Critical Care Medicine. Sepsis, a systemic response to infection, previously referred to as the **systemic inflammatory response syndrome (SIRS),** is now further defined to include sepsis associated with **hypoperfusion** or **hypofunction** (decreased function) or new organ dysfunction or abnormal performance (**severe sepsis**) or hypotension (**septic shock**). Despite the advances in laboratory diagnostics and medical treatment, there remain no clear, reliable laboratory-based criteria for the absolute prediction of a patient's response and outcome associated with a bloodstream infection.

Etiology

As previously mentioned, all major groups of microbes can be present in the bloodstream during many diseases.

Bloodstream infections are classified as **health care–associated infections (HAIs),** including **device-associated infections (DAIs)** such as **central line–associated bloodstream infections (CLA-BSIs),** or **community-acquired bloodstream infections (CA-BSIs).** A health care–associated bloodstream infection is defined as a positive blood culture that occurs 2 days or longer after admission to the health care facility. Conversely a CA-BSI is defined as an infection that occurs in the community or before 2 days of admission to the facility or hospitalization. Although the definition seems clear, the changes in patient demographics (the increasing numbers of immunocompromised individuals) and the changes in health care delivery associated with outpatient clinics for the treatment of cancer, acquired immune deficiency syndrome (AIDS), and other debilitating diseases makes the distinction difficult.

CA-BSIs can be subdivided into two groups: patients who are being treated with serious comorbid conditions such as cancer or diabetes or have immunosuppression (AIDS or immunosuppressive therapy associated with organ transplants) that require permanent intravenous (IV) devices, surgical treatments, or hemodialysis and those patients without any previous underlying condition who simply acquire an infection related to a localized or foci of infection, such as an abscess. The difference between the two groups is that patients in the second group are typically infected with antibiotic-susceptible organisms, whereas patients with comorbid conditions typically are infected with antibiotic-resistant organisms.

• BOX 67.1 Organisms Commonly Isolated From Blood Cultures

Staphylococcus aureus
Escherichia coli
Staphylococcus epidermidis
Other coagulase-negative staphylococci
Enterococcus spp.
Candida albicans
Pseudomonas aeruginosa
Klebsiella pneumoniae
Viridans streptococci
Streptococcus pneumoniae
Enterobacter cloacae
Proteus spp.
Beta-hemolytic streptococci
Anaerobic bacteria: *Bacteroides* and *Clostridium* spp.

As previously mentioned, all major groups of microbes can be present in the bloodstream during many diseases. However, HAIs are most often associated with the presence of an intravascular catheter or other device, surgical site infection, or invasive procedure in an anatomic site that contains microorganisms (microbiota) such as the gastrointestinal tract. Most cases of severe sepsis are associated with either bacterial or fungal organisms that are acquired from the patient's normal microbiota.

Bacteria

The organisms most commonly isolated from blood include *Staphylococcus aureus, Streptococcus pneumoniae,* and *Escherichia coli.* Other organisms associated with bloodstream infections are likely to be inhabitants of the health care environment and/or colonize the skin, oropharynx, and gastrointestinal tract of patients. The most common cases of secondary sepsis associated with a primary site of infection are identified in patients with lung or abdominal infections. Some of the most common, clinically significant organisms isolated from blood cultures are listed in Box 67.1. In general, the number of fungi and coagulase-negative staphylococci has increased, whereas the number of clinically significant anaerobic isolates has decreased.

Localized anatomic infections may lead to bacteremia or **toxemia** (circulating bacterial products) that stimulate a systemic inflammatory response. For example, *Neisseria meningitidis* is capable of growth in the bloodstream inducing DIC, severe sepsis, and eventually septic shock. Of importance, the laboratory isolation of certain bacterial species from blood can indicate the presence of an underlying, occult, or undiagnosed neoplasm. Alterations in local conditions at the site of a neoplasm may allow the bacteria to proliferate and seed the bloodstream. Another possible mechanism is reduced killing of bacterial cells by the host phagocytes. Organisms associated with neoplastic disease include *Clostridium septicum, Clostridium tertium,* and other uncommonly isolated clostridial species; *Streptococcus gallolyticus (S. bovis* group); *Aeromonas hydrophila* subsp. *hydrophilia; Plesiomonas shigelloides;* and *Campylobacter* spp. Finally, if *Streptococcus anginosus* group (*S. anginosus, Streptococcus constellatus*, and *Streptococcus intermedius*) bacteria are isolated from blood, the possibility of an abscess should be considered.

Fungi

Fungemia (the presence of fungi in blood) is usually a serious condition, occurring primarily in immunosuppressed patients and in those with serious or terminal illness. *Candida albicans* is by far the most common species isolated from bloodstream infections; however, a variety of species have been identified. *Candida* spp. infection is often associated with long-term hospitalization, intravascular catheters, diabetes, and other malignancies and correlates with the length of hospitalization. *Candida* spp. can form biofilm (an extracellular polysaccharide material) that permits hematogenous spread of the organism and provides a high level of antibiotic resistance (Chapter 62). *Malassezia furfur* can often be isolated in patients, particularly neonates, receiving lipid-supplemented parenteral nutrition.

Except for *Histoplasma,* which multiply in leukocytes (white blood cells), fungi do not invade blood cells, but their presence in the blood usually indicates a focus of infection elsewhere in the body. Fungi in the bloodstream can disseminate to all organs of the host, where they may grow, invade normal tissue, and produce toxic products. Fungi gain entrance to the circulatory system via loss of integrity of the gastrointestinal or other mucosa; through damaged skin; from primary sites of infection, such as the lung or other organs; or by means of intravascular catheters.

Systemic fungal infections begin as pneumonia and may disseminate from the lungs, which serve as the portal of entry. Arthroconidia of *Coccidioides* spp. and microconidia of *Histoplasma capsulatum* and *Blastomyces dermatitidis* are ingested by alveolar macrophages in the lung. These macrophages carry the fungi to nearby lymph nodes, usually the hilar nodes. The fungi multiply within the node tissue and ultimately are released into the circulating blood, from which they can seed other organs or are destroyed by the body's defenses. Molds are particularly insensitive to host defenses such as antibody and phagocytic cells because of their large size and their sterol-containing cell wall structure.

Parasites

Eukaryotic parasites may be found transiently in the bloodstream as they migrate to other tissues or organs. Their presence, however, cannot be considered consistent with a state of good health. For example, tachyzoites of the parasite *Toxoplasma gondii* may be found in circulating blood. They invade cells within lymph nodes and other organs, including the lungs, liver, heart, brain, and eyes. The resulting cellular destruction accounts for the manifestations of toxoplasmosis. Also, microfilariae are seen in peripheral blood during infection with *Mansonella, Loa loa, Wuchereria,* or *Brugia.*

Malarial parasites invade host erythrocytes and hepatic parenchymal cells. The significant anemia and subsequent tissue **hypoxia** (reduction in oxygen levels) may result from destruction of red blood cells by the parasite. Vascular trapping of normal erythrocytes by the infected red blood cells, which are less flexible and tend to clog small capillaries, is a major cause of morbidity. The host's immunologic response is to remove the parasites and damaged red blood cells; the immune response may also have deleterious effects.

Parasites in the bloodstream are usually detected by direct visualization, however some specialized laboratories have developed nucleic acid-based tests that include polymerase chain reaction (PCR) and direct probe methods that are particularly useful when there is a low parasitemia or the identification of the organism is questionable by microscopy (Chapter 48). Those parasites for which traditional diagnosis is predominantly dependent on observation of the organism in peripheral blood smears include *Plasmodium, Trypanosoma,* and *Babesia.* Patients with malaria or filariasis may display a periodicity in their episodes of fever that allows the physician to time the collection of blood for microscopic examination intended for optimal detection. Rapid serologic methods and molecular methods are currently used to detect malaria, babesiosis, and trypanosomiasis. These tests are described in Chapter 48.

Viruses

Although many viruses do circulate in the peripheral blood at some stage of disease, the primary pathology relates to infection of the target organ or cells. Those viruses that preferentially infect blood cells are Epstein-Barr virus (invades lymphocytes), cytomegalovirus (invades monocytes, polymorphonuclear cells, and lymphocytes), and human immunodeficiency virus (HIV) (involves CD4+ T lymphocytes and macrophages) and other human retroviruses that attack lymphocytes. The pathogenesis of viral diseases of the blood is the same as that for viral diseases of any organ; by diverting the cellular machinery to create new viral components or by other means, the virus may prevent the host cell from performing its normal function. The cell may be destroyed or damaged by viral replication, and immunologic responses of the host may also contribute to the pathogenesis.

Although many viral diseases have a viremic stage, recovery of virus particles or detection of circulating viruses is used in the diagnosis of only a few diseases. Chapter 64 discusses the recovery of viruses from blood in greater detail.

Types of Bacteremia

Bacteremia may be transient, continuous, or intermittent. Most people have experienced **transient** (asymptomatic and a result of a procedure associated with a nonsterile anatomic site) bacteremia; teething infants and people having dental procedures have had oral microbiota gain entry to the bloodstream through breaks in the gums. Other conditions in which bacteria are transiently present in the bloodstream include manipulation of infected tissues, devices or instrumentation inserted through contaminated mucosal surfaces, and surgery involving nonsterile sites. These circumstances may also lead to significant septicemia, although normally the bacteria are cleared from the blood by scavenging leukocytes, resulting in no infection. Septicemia can occur when the bacteria multiply more rapidly than the immune system is capable of killing and removing the organism.

In septic shock, bacterial endocarditis, and other endovascular infections, organisms are released into the bloodstream at a constant rate (**continuous bacteremia**). Also, during the early stages of specific infections, including typhoid fever, brucellosis, and leptospirosis, bacteria are continuously present in the bloodstream. Septic shock typically presents in two clinical stages: vasoconstriction and low cardiac output followed by vasodilation resulting in increased vascular resistance and cardiac output that causes systemic organ damage.

In most other infections, such as in patients with undrained abscesses, bacteria can be found **intermittently** (periodically present at various time intervals) in the bloodstream. Of note, the causative agents of meningitis, pneumonia, pyogenic arthritis, and osteomyelitis are often recovered from blood during the early course of these diseases. In the case of intermittent seeding of the blood from a sequestered focus of infection, such as an abscess, bacteria are released into the blood approximately 45 minutes before a febrile episode.

The symptoms of sepsis or septicemia are fever, chills, and malaise; these are caused by the presence of the invading microorganism and the toxins produced by these microorganisms. The older the patient is, the greater the risk and the rate of mortality because of septicemia.

Types of Bloodstream Infections

The two major categories of bloodstream infections are **intravascular** (those that originate within the cardiovascular system) and **extravascular** (those that result from bacteria entering the blood circulation through the lymphatic system from another site of infection). Of note, other organisms, such as fungi, may also cause intravascular or extravascular infections. However, because bacteria account for most significant vascular infections, these types of bloodstream infections are discussed in more detail. Factors contributing to the initiation of bloodstream infections are immunosuppressive agents, widespread use of broad-spectrum antibiotics that suppress the normal microbiota and allow the emergence of resistant strains of bacteria, invasive procedures that allow bacteria access to the interior of the host, more extensive surgical procedures, and prolonged survival of debilitated and seriously ill patients.

Intravascular Infections

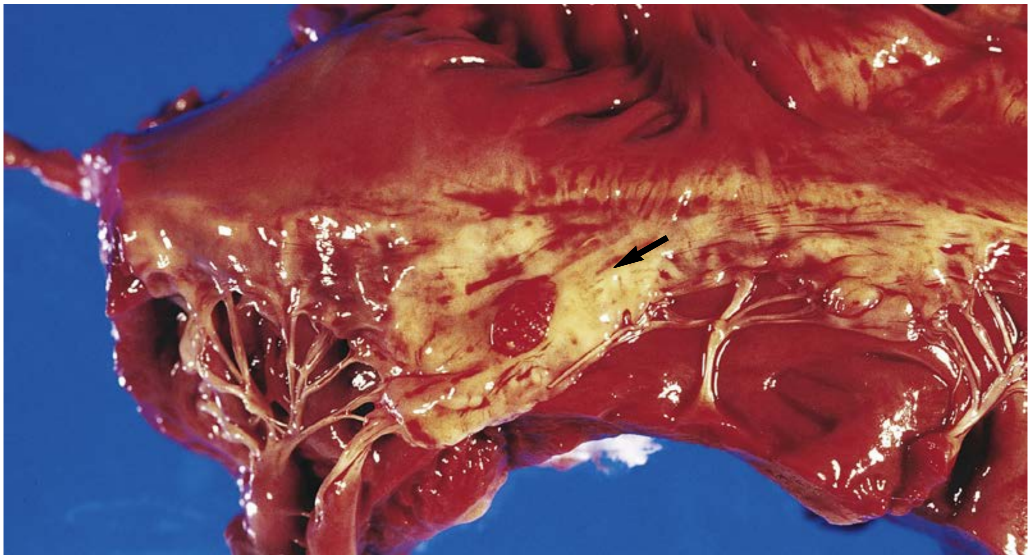
Intravascular infections include infective endocarditis, mycotic aneurysm, suppurative thrombophlebitis, and IV catheter–associated bacteremia. Because these infections are within the vascular system, organisms are present in the bloodstream at a constant rate (i.e., a continuous bacteremia). These infections in the cardiovascular system are extremely serious and considered life threatening.

Endocarditis

The development of **infective endocarditis** (infection of the endocardium most commonly caused by bacteria) is believed to involve several independent events. Cardiac abnormalities, such as congenital valvular diseases that lead to turbulence in blood flow or direct trauma from IV catheters, can damage cardiac endothelium. This damage to the endothelial surface results in the deposition of platelets and fibrin. If bacteria transiently gain access to the bloodstream (this can occur after an innocuous procedure such as brushing the teeth) after alteration of the capillary endothelial cells, the organisms may stick to and then colonize the damaged cardiac endothelial cell surface. After colonization, the surface will rapidly be covered with a protective layer of fibrin and platelets. This protective environment is favorable to further bacterial multiplication. This web of platelets, fibrin, inflammatory cells, and entrapped organisms is called a **vegetation** (Fig. 67.1). The resulting vegetation ultimately seeds bacteria into the blood at a slow but constant rate.

The primary causes of infective endocarditis are the viridans streptococci, comprising several species (Box 67.2). These organisms are normal inhabitants of the oral cavity, often gaining entrance to the bloodstream because of gingivitis, periodontitis, or dental manipulation. Heart valves, especially those that have been previously damaged, present convenient surfaces for attachment of these bacteria. *Streptococcus sanguis* and *Streptococcus mutans* are commonly isolated in streptococcal endocarditis. Gram-negative bacilli, known as the HACEK group, *Aggregatibacter aphrophilus, Actinobacillus actinomycetemcomitans, Cardiobacterium* spp., *Eikenella corrodens,* and *Kingella kingae,* can also be associated with endocarditis.

With the ever-increasing use of IV catheters, arterial lines, and vascular prostheses, organisms considered normal or health care–associated inhabitants of the human skin can gain access to the bloodstream and attach to various surfaces, including heart valves and vascular endothelium. It has been estimated that more than 200,000 health care–associated bloodstream infections occur annually in the United States in adults and children. Most of these infections are caused by the use of intravascular catheters. *Staphylococcus epidermidis* and other coagulase-negative staphylococci have been increasingly implicated as the cause of infection associated with intravascular catheters. *S. epidermidis* is the most common etiologic agent identified in prosthetic valve endocarditis, with *S. aureus* being the second most common. *S. aureus* is an important cause of septicemia without endocarditis and is found in association with other foci, such as abscesses, wound infections, and pneumonia, as well as sepsis related to indwelling intravascular catheters.



• **Fig. 67.1** Vegetations of bacterial endocarditis. *Arrow* indicates the vegetations. (Courtesy Celeste N. Powers, MD, PhD, Virginia Commonwealth University Medical Center, Medical College of Virginia Campus, Richmond, VA.)

• BOX 67.2 Agents of Infective Endocarditis

Aggregatibacter aphrophilus
Viridans streptococci[a]
  Abiotrophia spp. and *Granulicatella* spp. (previously referred to as nutritionally deficient streptococci)

Streptococcus bovis
Staphylococcus aureus[a]
Staphylococci (coagulase-negative)
Enterobacterales
Pseudomonas spp. (usually in drug users)
Haemophilus spp.
Unusual gram-negative bacilli (e.g., *Actinobacillus, Cardiobacterium, Eikenella, Coxiella burnetii*)
Yeast
Other (including polymicrobial infectious endocarditis)

[a] Most common organisms associated with native valve endocarditis in non–drug-using adults.

Mycotic Aneurysm and Suppurative Thrombophlebitis

Two other intravascular infections, mycotic aneurysms and suppurative thrombophlebitis, result from damage to the endothelial cells lining blood vessels. With respect to mycotic aneurysm, an infection causes inflammatory damage and weakening of an arterial wall; this weakening causes a bulging of the arterial wall (i.e., aneurysm) that can eventually rupture. The etiologic agents are similar to those that cause endocarditis.

Suppurative thrombophlebitis is an inflammation of a vein wall. The pathogenesis of this intravascular infection involves an alteration in the vein's endothelial lining followed by clot formation. The site is then seeded with organisms, thereby establishing a primary site of infection. Suppurative thrombophlebitis represents a common complication of hospitalized patients caused by the increasing use of IV catheters.

Intravenous Catheter–Associated Bacteremia. IV catheters are an integral part of the care for many hospitalized patients. For example, central venous catheters are used to administer fluids, blood products, medications, antibiotics, and nutrition and for hemodynamic monitoring. Unfortunately, a major consequence of these medical devices is colonization of the catheter by either bacteria or fungi, which can lead to catheter infection and a serious bloodstream infection. This consequence is a major source of health care–associated illness and death.

IV catheter–associated bacteremia (or fungemia) is believed to occur primarily by two routes (Fig. 67.2). The first route involves the movement of organisms from the catheter entry site through the patient's skin and down the external surface of the catheter to the catheter tip within the bloodstream. After arriving at the tip, the organisms multiply and may cause a bacteremia. The second way that IV catheter–associated bacteremia may occur is by migration of organisms along the inside of the catheter (the lumen) to the catheter tip. The catheter's hub, where the tubing connects into the IV catheter, is considered the site at which organisms gain access to the patient's bloodstream through the catheter lumen. The most common etiologic agents for IV catheter–associated bloodstream infections, regardless of the route of infection, are organisms found on the skin (Box 67.3). Certain strains of *Staphylococcus* spp. appear to be uniquely suited for causing catheter-related infections because of their ability to produce a biofilm or slime that consists of complex polysaccharides believed to help the organism adhere to the catheter's surface. The initial attachment of *Staphylococcus* spp. to the catheter's polystyrene surface is related to a cell surface protein. Once attached, the organism proliferates, subsequently forming a biofilm. Uncommon routes of IV catheter–tip infection include contaminated fluids or bloodborne seeding from another infection site.

Extravascular Infections

Except for intravascular infections, bacteria usually enter the circulation through the lymphatic system. Most cases of clinically significant bacteremia are a result of extravascular infection. When organisms multiply at a local site of infection such as the lung, they are drained by the lymphatics and reach the bloodstream. In most individuals, organisms in the bloodstream are effectively and rapidly removed by the reticuloendothelial system in the liver, spleen, and bone marrow and by circulating phagocytic cells. Depending on the extent of immunologic control of the infection, the organism may be circulated more widely, thereby causing a bacteremia or fungemia.

The most common portals of entry for bacteremia are the genitourinary tract (25%), respiratory tract (20%), abscesses (10%), surgical wound infections (5%), biliary tract (5%), miscellaneous sites (10%), and uncertain sites (25%). For the most part, the probability of bacteremia occurring from an extravascular site depends on the site of infection, its severity, and the organism. For example, any organism producing meningitis is likely to produce bacteremia at the same time. Of importance, certain organisms causing extravascular infections commonly invade the bloodstream; some of these organisms are listed in Table 67.1. In addition to these organisms, many other bacteria and fungi that cause extravascular infections are also capable of invading the bloodstream. Whether these organisms invade the bloodstream depends on the host's ability to control the infection and the organism's pathogenic potential. Some of the organisms associated with potential bloodstream infections from a localized site include members of the Enterobacterales, *S. pneumoniae, S. aureus, Neisseria gonorrhoeae,* anaerobic cocci, *Bacteroides, Clostridium, Klebsiella,* beta-hemolytic streptococci, and *Pseudomonas.* These are only some of the organisms commonly isolated from blood. Almost every known bacterial species and many fungal species have been implicated in extravascular bloodstream infections.

Clinical Manifestations

As previously discussed, bacteremia may indicate the presence of a focus of disease, such as intravascular infection, pneumonia, or liver abscess, or it may represent transient release of bacteria into the bloodstream. Septicemia or sepsis indicates a condition in which bacteria or their products (toxins) are causing harm to the host. Unfortunately,

TABLE 67.1 **Organisms Commonly Associated With Bloodstream Invasion From Extravascular Sites of Infection**

Organism	Extravascular Site of Infection
Anaerobic organisms	Wound, soft tissue
Brucella spp.	Reticuloendothelial system
Candida albicans	Genitourinary tract
Chlamydia pneumoniae	Respiratory
Clostridium spp.	Wound, soft tissue
Coagulase negative staphylococci	Wound, soft tissue
Enterobacterales (*E. coli, Klebsiella* spp., *Enterobacter* spp., *Proteus* spp., *Enterococcus* spp.)	Genitourinary tract infections, CNS
Haemophilus influenzae	Meninges (CNS), epiglottitis, periorbital region, respiratory
Legionella spp.	Respiratory
Listeria monocytogenes	Meninges (CNS)
Neisseria meningitidis	Meninges (CNS)
Pseudomonas aeruginosa	Wound, soft tissue, CNS
Salmonella enterica Typhi	Small intestine, regional lymph nodes of the intestine, reticuloendothelial system
Streptococcus pneumoniae	Meninges (CNS), respiratory
Streptococcus pyogenes	Wound, soft tissue
Staphylococcus aureus	Wound, soft tissue, meninges (CNS)

CNS, Central nervous system.

clinicians often use the terms bacteremia and septicemia interchangeably. Signs and symptoms of an SIRS may include fever or hypothermia (low body temperature), chills, hyperventilation (abnormally increased breathing leading to excess loss of carbon dioxide from the body) and subsequent respiratory alkalosis (a condition caused by the loss of acid leading to an increase in pH), skin lesions, change in mental status, and diarrhea. Sepsis is a form of SIRS with an identifiable infection. SIRS is classified as severe sepsis once the infection leads to organ or tissue damage and dysfunction. More serious manifestations include hypotension or shock, DIC, and major organ system failure. The syndrome known as septic shock, as previously mentioned, is characterized by fever, acute respiratory distress, shock, renal failure, intravascular coagulation, and tissue destruction and can be initiated by either exotoxins or endotoxins. Septic shock is mediated by the production of cytokines from activated mononuclear cells, such as tumor necrosis factor and interleukins.

Shock is the gravest complication of septicemia. In septic shock, the presence of bacterial products and the host's response act to shut down major host physiologic systems. Clinical manifestations include a drop in blood pressure, increase in heart rate, functional impairment in vital organs (brain, kidney, liver, and lungs), acid-base alterations, and bleeding problems. Gram-negative bacteria contain a substance in their cell walls, called endotoxin, which has a strong effect on several physiologic functions. This substance, a lipopolysaccharide (LPS) that composes part of the cell wall structure (Chapter 2), may be released during the normal growth cycles of bacteria or after the destruction of bacteria by host defenses. Endotoxin (or the core of the LPS, lipid A) has been shown to mediate numerous systemic reactions, including a febrile response, and the activation of complement and certain blood-clotting factors. Although gram-positive bacteria do not contain the lipid A endotoxin, many produce **exotoxins** (bacterial products secreted into the environment), and the effects of their presence in the bloodstream may be equally devastating to the patient.

DIC is a disastrous complication of sepsis. DIC is characterized by numerous small blood vessels becoming clogged with blood clots and bleeding because of the depletion of coagulation factors. DIC can occur with septicemia involving any circulating pathogen, including parasites, viruses, and fungi, although it is most commonly a consequence of gram-negative bacterial sepsis.

Immunocompromised Patients

One of the greatest challenges facing microbiologists is the handling of blood cultures from immunocompromised patients. The number of immunocompromised patients has steadily increased in recent years in large part as the result of advances in medicine. People undergoing organ transplantation, elderly persons, individuals with malignant disease (e.g., malignancies and cancer), and those receiving therapy for the malignancy are examples of immunosuppressed patients. AIDS has also contributed to the increase in the number of immunocompromised or immunosuppressed individuals. The marked immunosuppression brought about by infection with the HIV in patients with AIDS is a result of this virus' profound impairment of cellular immunity. Patients with AIDS have the greatest diversity of pathogens recovered from blood, including mycobacterial species, *Bartonella henselae, Corynebacterium jeikeium, Shigella flexneri,* unusual *Salmonella* spp., *H. capsulatum, Cryptococcus* spp., and cytomegalovirus.

As is typically observed in other hospitalized patients, organisms such as gram-positive aerobic bacteria (e.g., *S. aureus, Enterococcus*) and gram-negative aerobic bacteria (e.g., Enterobacterales, *Pseudomonas aeruginosa*) are common causes of bloodstream infections in immunocompromised patients. In addition, bloodstream infections in immunocompromised patients are commonly caused by either unusual pathogens whose recovery from blood requires special techniques or by organisms normally considered contaminants when isolated from blood cultures. Therefore microbiologists must be aware of the potential pathogenicity of organisms in immunosuppressed patients that are typically considered as probable blood culture contaminants. Without this knowledge, aerobic gram-positive rods isolated from blood cultures may be dismissed as contaminating diphtheroids, when, in fact, the organism is *C. jeikeium,* known to cause bacteremia in immunosuppressed patients. Microbiologists must be familiar with the unusual pathogens isolated from blood cultures obtained from immunocompromised patients and organisms that require special techniques for isolation (some of the special considerations are covered later in this chapter).

Detection of Bacteremia

Mortality rates associated with bloodstream infection range from 30% to 50%. Because bacteremia typically represents a life-threatening infection, the prompt detection and recovery of microorganisms from blood is of paramount importance. However, even with the advanced improvement in laboratory diagnostic methods, approximately 30% of all blood culture isolates do not have a directly linked identifiable source of infection. This leads to difficulties in the effective diagnosis and treatment of bloodstream infections.

To detect bloodstream infections, a patient's blood must be obtained by aseptic venipuncture and then incubated in culture media. Bacterial growth can be detected using techniques ranging from manual (in underdeveloped countries) to automated methods. After sufficient growth the organism's phenotypic (biochemical profile), nucleic acid, or protein spectrum is identified as a specific organism, and if it is considered pathogenic or treatment is necessary for the patient, the organism is then tested for susceptibility to various antimicrobial agents.

Specimen Collection

Preparation of the Site

Because blood culture media have been developed as enrichment broths to encourage the multiplication of as few as a single organism, these media will enhance growth of contaminating organisms, including normal microbiota of human skin. Therefore careful skin preparation before collecting the blood sample is of paramount importance to reduce the risk of introducing contaminants into blood culture media.

The vein from which the blood is to be drawn must be chosen before the skin is disinfected. If a patient has an existing IV line, the blood should be drawn below the existing line; blood drawn above the line will be diluted with fluid being infused. It is less desirable to draw blood through a vascular shunt or catheter because these prosthetic devices are difficult to decontaminate completely and may be colonized with a microbial biofilm within the vasculature of the patient.

Antisepsis

Once a vein is selected, the skin site is defatted (fat removal) with 70% isopropyl alcohol, and an antiseptic is applied to kill surface and subsurface bacteria. Regardless of the antiseptic used, it is critical to follow the manufacturer's recommendation for the length of time the antiseptic can remain on the skin. Available data indicate that iodine tincture (iodine in alcohol) and chlorhexidine are equivalent for skin preparation before drawing blood cultures. The steps necessary for drawing blood for culture are given in Evolve Procedure 67.1, which can be found on the Evolve site.

As part of ongoing quality assurance, laboratories should determine the rate of blood culture contamination by clinically evaluating patients' conditions in conjunction with the organism isolated from culture. Laboratories that recover contaminants at rates greater than 3% should suspect improper phlebotomy techniques and should institute measures to educate the phlebotomists in proper skin preparation methods. Higher infection rates may occur in specialty hospitals or long-term centers for critically ill patients.

Precautions

Standard precautions require that phlebotomists wear gloves for blood drawing. Because blood for culture must be obtained aseptically, it is important that contaminated surfaces that might come in contact with the venipuncture site be disinfected. For example, if the site must be touched after preparation, the phlebotomist must disinfect the gloved fingers used for palpation. Also, if the rubber stopper or septum of the container into which blood is to be inoculated (e.g., test tubes or commercial culture bottles) is potentially contaminated, the phlebotomist must disinfect the septum.

Specimen Volume

Adults

For many years, it has been recognized that most bacteremia in adults have a low number of colony-forming units (CFU) per milliliter (mL) of blood. For example, in several studies, fewer than 30 CFU/mL of blood were commonly found in patients with clinically significant bacteremia. Therefore a sufficient sample volume is critical for the successful detection of bacteremia.

There is a direct relationship between the volume of blood and an increased probability that the laboratory will isolate the infecting organism. Therefore collection of two to four sets of cultures using 10 to 20 mL of blood per culture may be required to properly identify and diagnose bloodstream infections in adults.

Children

It is not safe to take large samples of blood from children, particularly infants. The optimal volume of blood required for successful identification of organisms from infants and children has not been clearly delineated. Similar to adults, this patient population has low-level (small numbers of organisms) bacteremia or fungemia. Considering the low levels of circulating organisms in infants and children and based on the premise that it is safe to obtain as much as 4% to 4.5% of a patient's known total blood volume for culture and the relationship between blood volume and patient weight, for infants and small children, only 1 to 5 mL of blood should be drawn for culture. In addition, blood volumes drawn for culture should be closely monitored and reduced as necessary in anemic patients. Blood culture bottles are available that are designed specifically for pediatric patients. Because blood specimens from septic children may yield fewer than 5 CFU/mL of the organism, quantities less than 1 mL may not be adequate to detect pathogens. Nevertheless, smaller volumes should still be cultured, because high levels of bacteremia (more than 1000 CFU/mL of blood) are detected in some infants. If a bloodstream infection is suspected, all the blood should be placed in an aerobic pediatric bottle, because young patients are at a much lower risk of infection by anaerobic organisms.

Number of Blood Cultures

Because periodicity of microorganisms in the bloodstream may be characteristic for some diseases, continuous for some and random in others, patterns of bacteremia must be considered in establishing standards for the timing and number of blood cultures. If the volume of blood is adequate, usually two or four sets of blood cultures are sufficient to achieve the optimum blood culture sensitivity. A single blood culture is not sufficient for ruling out infection, whereas a second blood culture frequently establishes the diagnosis in at least 80% to 90% of patients. Three separate blood collections of 16 to 20 mL each, and an additional blood culture or two taken on the second day, if necessary, detects most etiologic agents (96% to 98%) in the bloodstream. The rate of recovery reaches nearly 100% for the detection of pathogens following four blood cultures; however, it is important to consider all factors including clinical diagnosis and other patient conditions when considering the large amount of blood sample required for optimal testing. This presumes use of a culture system adequate for growth of the organism involved, which often entails extending the incubation period.

Timing of Collection

The timing of cultures is not as important as other factors in patients with intravascular infections, because organisms are released into the bloodstream at a constant rate. Because the timing of intermittent sepsis is unpredictable, it is generally accepted that three or four blood cultures should be spaced an hour apart. However, in most cases, no significant difference in the yield between multiple blood cultures obtained simultaneously or those obtained at intervals has been demonstrated. The overall volume of blood cultured is more critical to increasing organism yield than timing.

Regardless, blood should be transported immediately to the laboratory and placed into the incubator or instrument as soon as possible. With blood culture instrumentation, a delay beyond 2 hours can delay the detection of positive cultures.

Miscellaneous Matters

Anticoagulation

Blood drawn for culture must not be allowed to clot. If the infecting organism becomes entrapped within a clot, its presence may go undetected. Thus, blood drawn for culture may be either inoculated directly into the blood culture broth media or into a sterile blood collection tube containing an anticoagulant for transport to the laboratory for subsequent inoculation. Heparin, ethylenediaminetetraacetic acid (EDTA), and citrate inhibit numerous organisms and are not recommended for use. Sodium polyanethol sulfonate (SPS) in concentrations of 0.025% to 0.03% is the best anticoagulant available for blood cultures. As a result, the most commonly used preparation in blood culture media today is 0.025% to 0.05% SPS. In addition to its anticoagulant properties, SPS also inactivates lysozyme, is anticomplementary and antiphagocytic and interferes with the activity of some antimicrobial agents, notably aminoglycosides. SPS, however, may inhibit the growth of a few microorganisms, such as some strains of *Neisseria* spp., *Gardnerella vaginalis, Streptobacillus moniliformis,* and all strains of *Peptostreptococcus anaerobius.* Because of the inhibitory effect of SPS on some organisms in conjunction with the necessity for an additional step to transfer the blood to the ultimate culture bottles that increases the risk of exposure to bloodborne pathogens as well as contamination, using collection tubes instead of direct inoculation into culture bottles may compromise organism recovery. For these reasons, the use of intermediate collection tubes is discouraged.

Dilution

In addition to the volume of blood collected and type of medium chosen, the dilution factor for the blood in the medium must be considered. To conserve space and materials, it is desirable to combine the largest feasible amount of blood from the patient (usually 10 mL) with the smallest amount of medium that will still encourage the growth of bacteria and dilute out or inactivate the antibacterial components of the blood. Traditionally, a 1:10 ratio of blood to medium was required for successful bacterial growth; however, several new commercial media containing resins or other additives have demonstrated enhanced recovery with as low as a 1:4 ratio. For this purpose, a 1:4 ratio of blood to unmodified medium has been found to be adequate in conventional blood cultures. All commercial blood culture systems (discussed later in this chapter) specify the appropriate dilution.

Blood Culture Media

The diversity of organisms recovered from blood requires an equally diverse and large number of media to enhance the growth of these organisms. Basic blood culture media contain a nutrient broth and an anticoagulant. Several different broth formulations are commercially available. Most blood culture bottles available commercially contain trypticase soy broth. More specialized broth bases include Columbia, brain heart infusion, *Brucella* broth, or other enriched media.

Types of Blood Culture Bottles

The addition of penicillinase to blood culture media for inactivation of penicillin has been largely superseded by the availability of a resin-containing medium that inactivates most antibiotics nonselectively by adsorbing them to the surface of the resin particles. Resin-containing media may enhance isolation of staphylococci, particularly when patients are receiving bacteriostatic drugs. The BACTEC system (Becton Dickinson Microbiology Systems, Sparks, MD) offers several resin-containing media. In addition to resin-containing media, BacT/ALERT has a blood culture bottle with supplemented brain-heart infusion (BHI) broth containing activated charcoal particles that significantly increase the yield of microorganisms over standard blood culture media. In addition, resins or charcoal may be added to commercial media to absorb and inactivate antimicrobial agents in the patient's blood sample. Care should be exercised when interpreting Gram stains from resin- and charcoal-containing bottles. The additives may be confused with gram-positive organisms. In addition to the traditional BacT/ALERT culture media, bioMérieux now offers next generation Fastidious Antimicrobial Neutralization Plus media (FAN^{R}Plus). The media are supplemented with Adsorbent Polymeric Beads that neutralize antimicrobials but provide clearer Gram stains.

In general, each blood culture set includes a blood culture bottle designated for aerobic recovery and one for anaerobic recovery of bacteria. Because of the decline in the proportion of positive blood cultures yielding anaerobic bacteria coupled with the increasing pressure for laboratories to be cost effective, some investigators have recommended laboratories discard this routine practice of processing all blood samples aerobically and anaerobically. It has been proposed that anaerobic cultures should be selectively performed, and, in place of the anaerobic blood culture, a second aerobic bottle be included. Depending on the patient population served by the laboratory, numbers of blood cultures submitted, and personnel and financial resources, the laboratory may have one or more methods available to ensure detection of the broadest range of organisms in the least possible time.

Culture Techniques

Special blood culture broth systems are available for the isolation of mycobacteria. The systems are useful in detecting disseminated infections caused by *Mycobacterium tuberculosis* and no tuberculosis mycobacteria.

Conventional Blood Cultures

Incubation Conditions

The atmosphere in commercially prepared blood culture bottles is usually at a low oxidation-reduction potential, permitting the growth of most facultative and some anaerobic organisms. Constant agitation of the bottles during the first 24 hours of incubation enhances the growth of most aerobic bacteria.

Self-Contained Manual Culture Systems

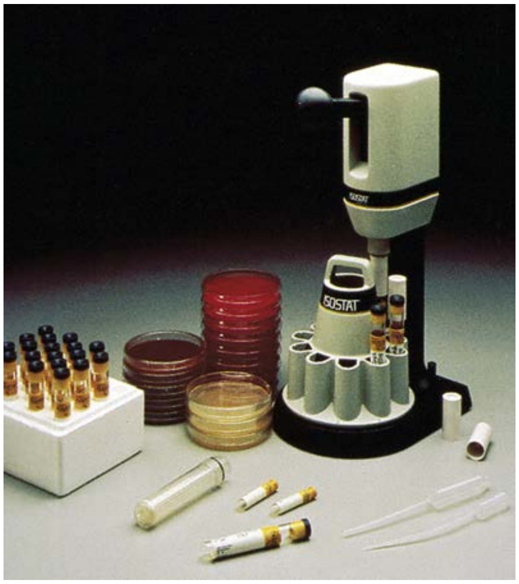
A modification of the biphasic blood culture medium is the BD BBL Septi-Chek system (Becton Dickinson Microbiology Systems, Sparks, MD) consisting of a conventional blood culture broth bottle with an attached chamber containing a slide coated with agar or several types of agars. Special media for isolation of fungi and mycobacteria are also available. To subculture, the entire broth contents are allowed to contact the agar surface by inverting the bottle, a simple procedure that does not require opening the bottle or using needles. The bottles should be tipped at least twice weekly to wash the liquid culture over the agar coated slide to culture any organisms that are growing in the broth. The large volume of broth subcultured and the enclosed method provide faster detection for many organisms than is possible with conventional systems. The Septi-Chek system appears to enhance the recovery of *S. pneumoniae,* but such biphasic systems do not efficiently recover anaerobic isolates, therefore requiring a second anaerobic bottle.

The Signal Blood Culture System (Thermo Fisher Scientific, Waltham, MA), is a single one-bottle system that can be used to isolate common aerobic, anaerobic, and microaerophilic organisms from both adults and pediatrics. The bottle contains 80 mL of broth and a detection chamber. The bottles are agitated and incubated at 35 to 37°C. When an organism begins to metabolize, the CO_2 formed by the microorganism increases pressure within the bottle pushing some of the blood specimen broth mixture through a needle that extends from the liquid into the Signal Detection Chamber. The presence of fluid in the detection chamber indicates a positive culture and can then be removed for additional testing such as Gram-stain or plating to solid media.

Both manual blood culture systems should be examined daily for growth. Growth within blood/broth is indicated by turbidity (visible using reflected or transmitted light), hemolysis, CO_2 (gas production), or visual growth on the surface or as flocculation.

Lysis Centrifugation

The Isolator/Isostat System Press and Rack (Alere, Waltham, MA) is a lysis centrifugation system that includes a hand-operated press used to apply a cap to the tube and is commercially available. The Isolator consists of a stoppered tube containing saponin to lyse blood cells and SPS as an anticoagulant (Fig. 67.3). After centrifugation, the supernatant is discarded, the sediment containing the pathogen is vigorously vortexed, and the entire sediment is plated to solid agar. Benefits of this system include rapid and improved recovery of filamentous fungi, the presence of actual colonies for direct identification and susceptibility testing after initial incubation, the ability to quantify the CFU present in the blood, rapid detection of polymicrobial infections, dispensing with the need for a separate antibiotic-removal step, the ability to choose special media for initial culture setup based on clinical impression (e.g., direct plating onto media supportive of *Legionella* spp. or *Mycobacterium* spp.),



• Fig. 67.3 Lysis centrifugation blood culture (Isolator/Isostat System, Alere, Waltham, MA) uses vacuum-draw collection tubes with a lysing agent and special apparatus (Isostat Press) to facilitate removal of the supernatant without the use of needles.

and potential enhanced recovery of intracellular microorganisms caused by lysis of host cells. Possible limitations of the system seem to be a relatively high rate of plate contamination and a decreased ability to detect certain bacteria, such as *S. pneumoniae, Listeria monocytogenes, Haemophilus influenzae,* and anaerobic bacteria, compared with conventional systems. If a mixed infection is suspected, an additional blood culture collection tube should be inoculated simultaneously.

Instrument-Based Systems

During these times of cost constraints in health care and a corresponding requirement for clinically relevant care, the development of improved instrumentation for blood cultures has improved the identification of the pathogens improving patient care. Instruments are capable of rapid and accurate detection of organisms in blood specimens. By using newer instrumentation, laboratories processing a large volume of blood cultures also provide results cost effectively.

BACTEC Systems

Many laboratories use the BACTEC system (Becton Dickinson Microbiology Systems, Sparks, MD), which measures the production of carbon dioxide (CO_2) by metabolizing organisms. Blood or sterile body fluid for routine culture is inoculated into bottles containing appropriate substrates.

The BACTEC blood culture systems are fully automated with the incubator, shaker, and detector all in one instrument. These fully automated blood culture systems use fluorescence to measure CO_2 released by organisms; a gas-permeable fluorescent sensor is on the bottom of each vial. As CO_2 diffuses into the sensor and dissolves in water present in the sensor matrix, hydrogen (H^+) ions are generated. These H^+ ions cause a decrease in pH, which, in turn, increases the fluorescent output of the sensor. There is continuous monitoring of each bottle, and detection is external to the bottle.

BacT/ALERT Microbial Detection System

Other laboratories use the BacT/ALERT System (bioMérieux, Durham, NC), which measures CO_2-derived pH changes with a colorimetric sensor in the bottom of each bottle. The sensor is separated from the broth medium by a membrane permeable to CO_2. As organisms grow, they release CO_2, which diffuses across the membrane and is dissolved in water present in the matrix of the sensor. As CO_2 is dissolved, free hydrogen ions are generated. These free hydrogen ions cause a color change in the sensor (blue to light green to yellow as the pH decreases); a sensor in the instrument reads this color change.

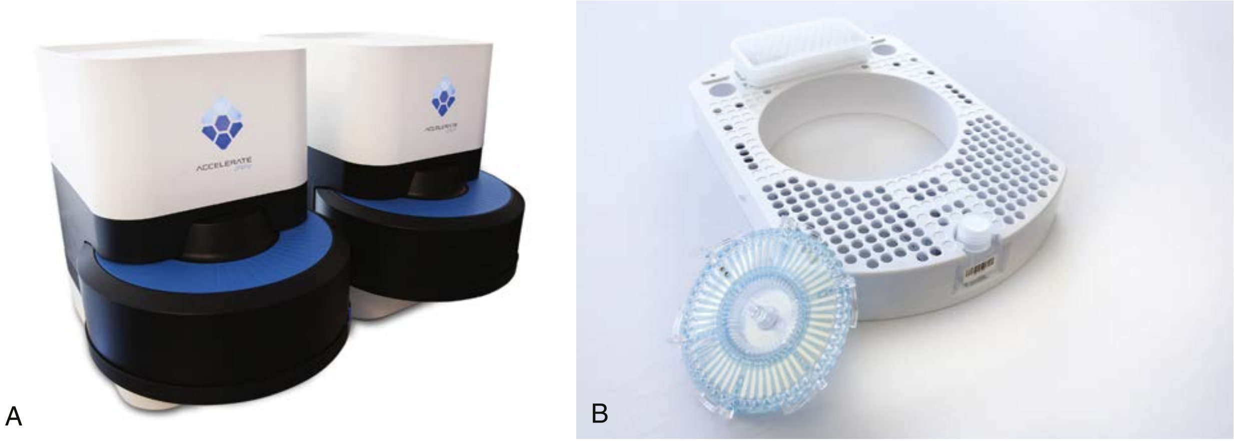
Versa TREK System

The Versa TREK system (Thermo Scientific, TREK Diagnostics, Cleveland, OH) uses a unique agitation system during blood culture inoculation. The aerobic media bottles each contain a small magnetic stir bar that enhances oxygenation during incubation. Like the other systems, this is also a continuously monitoring instrument.

Non–Culture Based Methods for the Identification of Bacteremia or Sepsis

Because blood culture systems are insensitive to rapid detection of bacteremia or sepsis, several biochemical markers have been used as indicators or biomarkers for diagnosis or prognosis in cases of bacteremia and sepsis. These biomarkers include chemicals made by or released into the bloodstream, such as beta-D-glucan, or galactomannan produced by fungal organisms to human interleukins (IL-10 and IL-1Ra), other immune response related molecules (i.e., presepsin, IL-6, monocyte chemoattractant protein), and physiological indicators including C-reactive protein, lactate, or procalcitonin. Procalcitonin assays have been widely used to monitor patients in clinical settings to assist in the identification of pathogens, predict mortality, and monitor the use of antibiotics and reduce the duration of therapy in bloodstream infections. Interleukins and other immune response related molecules rapidly rise when blood stream infections are present and can assist in the differentiation of other inflammatory conditions. The enzymatic detection of beta-D-glucan or enzyme immunoassays for circulating mannans are becoming increasingly used for the detection of invasive systemic fungal infections. In addition, various nucleic acid-based systems are also widely used for the direct detection of viral, fungal, and bacterial pathogens in the bloodstream.

Procalcitonin is secreted by the thyroid gland and neuroendocrine cells of the lungs and intestines. It is normally found in serum concentrations of less than 0.1 ng/mL in healthy individuals. Both the lung and intestinal cells



• **Fig. 67.4** (A) FDA-approved combination identification and antibiotic sensitivity system, the Accelerate Pheno system (Accelerate Diagnostics Inc, Tucson AZ). (B) Sample cartridge.

increase the production of procalcitonin in response to inflammation resulting in a rapid increase in the serum of up to 400 times the normal value or greater than 4 ng/mL. The values of procalcitonin in the serum have also been used as a prognostic indicator for bacterial infection in the presence of inflammation and the progression to severe sepsis. A serum level of less than 0.5 ng/mL indicates no risk of infection, 0.5 to 2.0 ng/mL moderate risk of infection, and 2 to 10 ng/mL indicates a high risk of infection and progression to severe sepsis.

The T2Candida system (T2 Biosystems, Inc., Lexington, MA) is a magnetic resonance assay combined with nucleic acid amplification of five major *Candida* species. The system can be utilized to identify invasive *Candida* species in adults as well as small-volume blood specimens from pediatric patients within 5 hours.

Two FDA-cleared nucleic acid systems, the Verigene assay (Luminex, Austin, TX) and the BioFire FilmArray Blood Culture Identification panel (bioMérieux, Inc, Durham, NC), have demonstrated reported concordance with clinical results from 86% to 100% depending on the infectious agent. The BioFire FilmArray Blood Culture Identification Panel, or BCID, contains 27 targets that include yeast and gram-positive and gram-negative bacteria commonly isolated from bloodstream infections. In addition, the assay detects three antibiotic resistance genes associated with bloodstream infections: *mec A*, methicillin resistance; *vanA/B*, vancomycin resistance; and *KPC*, carbapenem resistance. The Verigene assay has separate assays for gram-positive (11 different species or genera) and gram-negative (9 different species or genera) organisms along with the detection of antimicrobial resistance genes including *mec A* and *vanA/B* in gram-positive organisms and extended-spectrum beta-lactamase (ESBL) and carbapenemase in gram-negative organisms.

Although most of the bloodstream infections are monomicrobic, polymicrobic infections do occur. The sensitivity for the detection of multiple pathogens directly from the bloodstream is limited. In addition, the nucleic acid-based methods require a follow-up culture to complete antimicrobial sensitivity testing. An FDA-approved combination system, the Accelerate Pheno system (Accelerate Diagnostics Inc, Tucson AZ), does not require a separate culture following identification of the bloodstream pathogen (Fig. 67.4). The system combines the identification of pathogens directly from the blood specimen within approximately 90 minutes followed by the antimicrobial sensitivity results in about 7 hours from the same sample. The system uses electrochemistry and proprietary gel technology to separate microorganisms from the matrix of molecules in the blood specimen. The cells are concentrated using electrokinetic concentration technology. The cells are captured in a flow cell and positioned for image capture and analysis as the organisms grow. The antibiotic sensitivity reports the minimal inhibitory concentration using morphokinetic cellular images by digital microscopy every 10 minutes in real time. The Accelerate Pheno system identifies 14 bacteria that include gram-positive and gram-negative pathogens and two *Candida* species from blood specimens with a reported approximate specificity and sensitivity of 98%.

Matrix-Assisted Laser Desorption Ionization Time-of-Flight Mass Spectrometry

MALDI-TOF MS has been successfully used to identify many organisms indirectly following pure colony isolation from blood cultures (Chapter 7). However, the antibiotic sensitivity testing requires additional overnight incubation and analysis prior to reporting to the primary care provider. Direct microorganism identification from blood cultures using MALDI-TOF has been successful but reports indicate that it has not improved the methods to complete antimicrobial sensitivity testing nor shortened the duration of antimicrobial therapy for patients with bloodstream infections.

Intravenous Catheter–Associated Infections

The insertion of an IV catheter during hospitalization is common practice. Infection, either locally at the catheter insertion site or sepsis caused by bacteremia, is one of the most common complications of catheter placement. IV catheters are easily contaminated by normal skin microbiota, as well as colonized by microorganisms capable of forming mono- or polymicrobial biofilms on the surface of the catheter tip. Because the skin of all patients is colonized with normal microbiota that are also common pathogens in catheters, techniques used to diagnose catheter-related infections attempt to quantitate bacterial growth. Diagnosis of an IV catheter–related bacteremia (or fungemia) is difficult, because there are often no signs of infection at the catheter insertion site, and the typical signs and symptoms of sepsis can overlap with other clinical manifestations; even the finding of a positive blood culture does not identify the catheter as the source. To date, various methods, such as semiquantitative cultures, Gram stains of the skin entry site, and culture of IV catheter tips following catheter removal are used to monitor potential IV catheter–associated infections. The terminal end of the IV catheter is removed and rolled several times across a blood agar plate. The tip is then removed from the agar plate and placed in enrichment broth. Both the plate and enrichment broth are incubated at 37°C for 18 to 24 hours. After inoculation, the blood agar plates are examined, and any isolates are identified according to the laboratory protocol. The enrichment broth may be subcultured to blood agar and anaerobic media for further analysis and potential detection of intraluminal colonization.

Handling Positive Direct Detection and Indirect Detection From Culture

Most laboratories use a broth-based automated blood culture method. When a positive culture is indicated according to the automated detection system including nucleic acid–based direct detection systems, a Gram-stained smear of an air-dried drop of the direct sample or blood culture medium should be performed. Methanol fixation of the smear preserves bacterial and cellular morphology, which may be especially valuable for detecting gram-negative bacteria among red cell debris. As soon as a morphologic description can be tentatively assigned to an organism detected in blood, the physician should be contacted and given all available information. Determining the clinical significance of an isolate is the physician's responsibility. If no organisms are seen on microscopic examination of a bottle that appears positive, the blood culture should be reincubated. In a patient, with high white blood cell counts, the cellular metabolism can create the production of metabolites including CO_2, causing a false-positive reaction in the automated systems.

Direct Rapid Tests from Blood Culture Bottles

Numerous rapid tests for identification and presumptive antimicrobial susceptibilities can be performed from the broth blood culture if a monomicrobic infection is suspected (based on microscopic evaluation). A suspension of the organism that approximates the turbidity of a 0.5 McFarland standard, obtained directly from the broth or by centrifuging the broth and resuspending the pelleted bacteria, can be used to perform either disk diffusion (qualitative) or broth dilution (quantitative) antimicrobial susceptibility tests. These suspensions may also be used to perform preliminary tests such as coagulase, thermostable nuclease, esculin hydrolysis, bile solubility, antigen detection by fluorescent-antibody stain or agglutination procedures for gram-positive bacteria, oxidase, and commercially available rapid identification kits for gram-negative bacteria. Presumptive results must be verified with conventional procedures using pure cultures.

In the event of possible future studies (e.g., additional susceptibility testing), isolates from blood cultures may be stored by freezing at −70°C in 10% skim milk. A commercial preservation system, Microbank beads, is available for the preservation and storage of bacterial and fungal isolates (Pro-Laboratory Diagnostics, Austin, TX). The vials contain pretreated beads and a cryopreservative solution that improves storage of microorganisms. Storing an agar slant of the isolate under sterile mineral oil at room temperature is a good alternative to freezing. It may be necessary to compare separate isolates from the same patient or isolates of the same species from different patients months after the bacteria were isolated.

Interpretation of Blood Culture Results

Because of the increasing incidence of blood and vascular infection caused by bacteria normally considered avirulent, indigenous microbiota of a healthy human host, interpretation of the significance of growth of such bacteria in blood cultures has become increasingly difficult. On one hand, contaminants may lead to unnecessary antibiotic therapy, additional testing and consultation, and increased length of hospital stay. Costs related to false-positive blood culture results (i.e., contaminants) are associated with 40% higher charges for IV antibiotics and microbiology testing. On the other hand, failure to recognize and appropriately treat indigenous microbiota can have dire consequences. Guidelines that can assist in distinguishing probable pathogens from contaminants are as follows:

- Probable contaminant
  - Growth of *Bacillus* spp., *Corynebacterium* spp., *Propionibacterium* spp., or *Cutibacterium* spp. in one of several cultures
    - Note: *Bacillus anthracis* must be ruled out before dismissing *Bacillus* species as a probable contaminant.
  - Growth of multiple organisms from one of several cultures (polymicrobial bacteremia is uncommon)
  - The clinical presentation or course is not consistent with sepsis
  - The organism causing the infection at a primary site of infection is not the same as that isolated from the blood culture
- Probable pathogen
  - Growth of the same organism in repeated cultures obtained either at different times or from different anatomic sites

- Growth of certain organisms in cultures obtained from patients suspected of endocarditis, such as enterococci, or gram-negative rods in patients with clinical gram-negative sepsis
- Growth of certain organisms such as members of Enterobacterales, *S. pneumoniae,* gram-negative anaerobes, and *Streptococcus pyogenes*
- Isolation of commensal microbiota from blood cultures obtained from patients suspected to be bacteremic (e.g., immunosuppressed patients or those with prosthetic devices)
- Type(s) of isolates recovered from other body sites and response to therapy.

Special Considerations for Other Relevant Organisms Isolated From Blood

The organisms discussed in this section require somewhat different conditions for their successful recovery from blood culture samples. Most of these organisms are rarely isolated from blood. Therefore it is important for the physician to notify the laboratory of remarkable patient history, such as travel abroad. It is also important the laboratory be aware of organisms isolated from blood cultures that are considered potential agents for bioterrorist attacks. These bacteria include *B. anthracis, Francisella tularensis, Brucella* spp., and *Yersinia pestis.* Finally, in addition to the organisms discussed later that require special conditions for isolation from blood, several organisms are unable to grow on artificial media and are best diagnosed by alternative methods such as serology or nucleic acid amplification assays; these organisms are listed in Box 67.4.

HACEK Bacteria

As mentioned earlier in the chapter, the term HACEK refers to a group of fastidious, gram-negative bacilli including *A. aphrophilus, A. actinomycetemcomitans, C. hominis, E. corrodens,* and *K. kingae.* Recovery of these organisms from blood cultures is usually associated with infective endocarditis. Other fastidious organisms, such as *Capnocytophaga* spp., *Rothia dentocariosa, Flavobacterium* spp., and *Chromobacterium* spp., may also be isolated from blood cultures. Continuous monitoring blood culture systems have indicated that almost all bloodstream infections with these organisms, including endocarditis, were detected within 5 days of incubation.

• BOX 67.4 Microorganisms That Cause Bloodstream Infections but Do Not Grow on Artificial Media

Coxiella burnetii
Chlamydia spp. (*C. pneumoniae* and *C. psittaci*)
Rickettsia spp.
Tropheryma whipplei

Campylobacter and *Helicobacter* spp.

Several species of *Campylobacter* and *Helicobacter* are occasionally isolated from blood cultures, usually growing within the 5-day incubation protocol. However, these organisms are small, thin, curved, gram-negative rods that may only be visualized using an AO stain after detection by continuous monitoring instruments. Because of the fastidious nature of these organisms, appropriate media and atmospheric conditions for subculture from blood culture bottles must be used (Chapter 33).

Fungi

Many fungi, particularly yeast, can be recovered in standard blood culture media if the bottle is incubated at the appropriate temperature and has been vented and agitated to allow sufficient oxygenation for fungal growth. However, some fungi may grow slowly and poorly in these media, which best support bacterial growth. Optimal isolation of fungi in blood cultures is achieved with either agitated incubation of a commercial biphasic system, such as the Septi-Chek, or by using the lysis centrifugation system. Manufacturers of media for automated blood culture systems have developed specific media for fungal isolation. These media formulas have dramatically increased the numbers of fungi isolated from patients with fungemia and have shortened the incubation time required for detection of the fungi. An increasing incidence of bloodstream infections with invasive *Candida* spp. and polymicrobial infections of *C. albicans* in combination with *S. aureus* has become a significant concern. Both organisms have demonstrated an increasing resistance to antimicrobials, posing serious treatment difficulties and increased mortality rates. Blood specimens for detecting fungemia are collected in the same manner as for bacterial culture.

Mycobacterium spp.

Patients with HIV infection can have disseminated infection with species of nontuberculous mycobacteria, predominantly *Mycobacterium avium* complex. HIV infections along with multidrug-resistant strains of *Mycobacterium* spp. result in high rates of mortality. Extra-pulmonary disease can become disseminated by entering the bloodstream and being carried to multiple sites throughout the body. Rapidly growing nontuberculosis species of *Mycobacterium* are also more frequently identified in bloodstream infections in immunocompromised patients.

Special media, such as Middlebrook 7H9 broth with 0.05% SPS or BHI broth with 0.5% polysorbate 80, with or without a Middlebrook 7H11 agar slant, enhances the recovery of *Mycobacterium* spp. In addition, the isolator system may also be used for growth of *Mycobacterium* spp.

The broth-based systems for the detection of *Mycobacterium* bloodstream infections provide a mechanism for continued monitoring, prevent cross-contamination, and provide a safer environment for laboratory personal. Despite the advantages, mycobacterial bloodstream infections can go undetected in automated broth culture systems.

Brucella spp.

Brucellosis is a common disease in many developing countries but is uncommon in developed countries. Because brucellosis may be included in the differential diagnosis of many infections, microbiologists should be prepared to process blood cultures suspected of having *Brucella;* blood cultures are positive in 70% to 90% of patients with brucellosis. Septicemia occurs primarily during the first 3 weeks of illness. Special handling may be required for recovering *Brucella* spp. from blood, because these organisms are fastidious, often slow-growing, intracellular parasites. Best recovery is obtained with *Brucella* broth or trypticase soy broth. The use of biphasic media may enhance growth, or the Isolator system may allow release of intracellular bacteria.

The use of continuous monitoring systems has enhanced recovery of *Brucella* spp. For example, the use of the BACTEC instruments makes possible the diagnosis of more than 95% of positive cultures within a 5-day period without routine subcultures of negative vials.

Spirochetes

Borrelia spp.

Visualization in direct preparations is diagnostic for 70% of cases of relapsing fever, a febrile disease caused by *Borrelia recurrentis.* Organisms may be seen in direct wet preparations of a drop of anticoagulated blood diluted in saline as long, thin, unevenly coiled spirochetes that seem to push the red blood cells around as they move. Thick and thin smears of blood, prepared as for malaria testing and stained with Wright's or Giemsa stain, are also sensitive for the detection of *Borrelia.*

Blood cultures using standard bacterial blood cultures incubated for 2 to 3 weeks have been successful for the identification of *B. burgdorferi*. Detection can be enhanced by periodically sampling culture aliquots and using nucleic acid amplification techniques.

Leptospira spp.

Leptospirosis can be diagnosed by isolating the causative spirochete from blood during the first 4 to 7 days of illness. Leptospires will grow 1 to 3 cm below the surface, usually within 2 weeks. The organisms remain viable in blood with SPS for 11 days, allowing for transport of specimens from distant locations. Direct dark-field examination of peripheral blood is not recommended, because many artifacts are present that resemble spirochetes. If blood must be shipped to a reference laboratory for culture, blood may be collected in heparin, oxalate, or citrate tubes and maintained at ambient temperature. One to two drops of blood are inoculated into semisolid oleic acid–albumin medium at the patient's bedside. Various commercial mediums are available, such as Fletcher's medium (BD Diagnostics, Sparks, MD). Multiple cultures are recommended to improve recovery of the organisms. *Leptospira* spp. do not grow well in conventional blood culture systems; molecular assays may improve detection of the organism, as may the use of serologic markers for rapid diagnosis. (Further information about *Borrelia* and *Leptospira* is provided in Chapter 45.)

Granulicatella and *Abiotrophia* spp.

Granulicatella spp. and *Abiotrophia* spp., previously known as nutritionally variant streptococci, are unable to multiply without the addition of 0.001% pyridoxal hydrochloride (also called thiol or vitamin B_6). These streptococci have been associated with bacteremia and endocarditis. Although human blood introduced into the blood culture medium provides enough of the pyridoxal to allow the organisms to multiply in the bottle, standard sheep blood agar plates may not support their growth. Subculturing the broth to a 5% sheep blood agar plate and either overlaying a streak of *S. aureus* or dropping a pyridoxal disk to produce the supplement generally allows colonies of the streptococci to grow as tiny satellites next to the streak. Some commercial media may be supplemented with enough pyridoxal (0.001%) to support growth of nutritionally variant streptococci.

Mycoplasma spp.

Invasive and systemic disease from *Mycoplasma* spp., including *M. hominis* and oral commensals are likely more prevalent than diagnosed. The use of automated blood culture continuously monitoring systems is not recommended for detection of *Mycoplasma* spp. The organisms are inhibited by SPS, the anticoagulant used in most automated blood culture media.

Bartonella spp.

Bartonella spp. have been reported to cause bacteremia and endocarditis in both immunocompetent and immunocompromised patients. *B. henselae* has also been linked to cat-scratch disease, a common infectious disease in the United States. Cat-scratch disease is characterized by a persistent necrotizing inflammation of the lymph nodes. Biphasic or broth culture systems may be used for the isolation of *Bartonella* spp., however the organisms rarely reach a high level of turbidity or activate the CO_2 detector in automated systems. Serology remains the most reliable method for diagnosis of *Bartonella* bacteremia.

Visit the Evolve site for a complete list of procedures, review questions, and case studies.

CASE STUDY 67.1

A college student was admitted to the hospital with fever and chills. He also appeared disoriented and complained of chest pain. Blood cultures were collected on admission, and he was prescribed cefazolin therapy. His condition worsened, and within 12 hours the blood cultures were reported positive for a gram-positive coccus, suggestive of *Staphylococcus* spp. Two hours later the laboratory confirmed the identification of *Staphylococcus aureus*. An echocardiogram was performed that showed multiple vegetations on his tricuspid and aortic valves (Fig. 67.1). Surgery was planned to repair the valves, but the patient died within 48 h of admission. It was discovered that the student had been injecting cocaine with his friends.

Questions

1. How did the laboratory identify the organism so quickly?
2. How many blood cultures should be submitted to diagnose bacteremia?
3. If the isolate had been coagulase negative, what would indicate that this was a true infection with the organism?

PROCEDURE 67.1

Drawing Blood for Culture

Principle

Organisms found in circulating blood can be enriched in culture for isolation and further studies. Blood for culture must be obtained aseptically. Once removed from the circulation, unclotted blood must be diluted in growth media.

Method

Note: Universal precautions require that phlebotomists wear gloves for this procedure.

1. Choose the vein to be drawn by touching the skin before it has been disinfected.
2. Using 70% alcohol, cleanse the skin over the venipuncture site, rubbing back and forth vigorously. Allow to air dry.
3. Starting in the center of the circle, apply chlorhexidine (or 2% tincture of iodine; povidone-iodine) rubbing back and forth until the area has been saturated with iodine. Allow the iodine to dry on the skin for at least 1 min. The timing is critical; a watch or timer should be used.
4. If the phlebotomist must touch the site after preparation, the phlebotomist must disinfect the gloved fingers used for palpation in identical fashion.
5. Insert the needle into the vein and withdraw blood. Do not change needles before injecting the blood into the culture bottle.
6. After the needle has been removed, the site should be cleansed with 70% alcohol again, because many patients are sensitive to iodine.

Chapter Review

1. Which of the following bacterial organisms is not associated with neoplastic disease?
   - **a.** *Clostridium septicum*
   - **b.** *Streptococcus bovis*
   - **c.** *Campylobacter* species
   - **d.** *Staphylococcus aureus*
2. If the *Streptococcus anginosus* group is isolated from blood, which of the following should be considered?
   - **a.** Neoplasm
   - **b.** Abscess
   - **c.** Production of toxins in the blood
   - **d.** Tissue hypoxia
3. What is the principal causative agent of fungemia?
   - **a.** *Coccidioides* spp.
   - **b.** *Blastomyces dermatitidis*
   - **c.** *Candida albicans*
   - **d.** *Histoplasma capsulatum*
4. What is the safe volume of blood to be drawn for pediatric blood cultures?
   - **a.** <1 mL
   - **b.** 1 to 5 mL
   - **c.** 5 to 10 mL
   - **d.** 10 to 20 mL
5. When collecting specimens for blood culture, without being able to directly inoculate the blood culture bottles or system, what is the best anticoagulant to use for transport to the laboratory?
   - **a.** Heparin
   - **b.** EDTA
   - **c.** Sodium citrate
   - **d.** SPS (sodium polyanethol sulfonate)
6. When collecting blood for blood culture from patients who have previously been on antibiotic therapy, what is the correct number of cultures to be drawn?
   - **a.** One blood culture collected on day 1, two blood cultures collected on day 2
   - **b.** Two sets of blood cultures collected at the same time, but from separate sites
   - **c.** Three separate blood cultures of 16 to 20 mL each, an additional one or two cultures may be required
   - **d.** None of the above is correct
7. When collecting a blood culture, it is acceptable to cleanse the collection site with:
   - **a.** Soap and H_2O
   - **b.** Alcohol swabs
   - **c.** Alcohol and iodine or chlorhexidine
   - **d.** All the above
8. DIC is a complication of bloodstream sepsis and is most often caused by:
   - **a.** Gram-negative bacteria
   - **b.** The virus CMV
   - **c.** Gram-positive bacteria
   - **d.** Parasites
9. The parasites for which diagnosis is dependent on observation of the organism in peripheral blood smears include all the following *except:*
   - **a.** *Plasmodium*
   - **b.** *Tropheryma whipplei*
   - **c.** *Trypanosoma*
   - **d.** *Babesia*
10. **True or False**

______ The timing of blood culture collection is a more important consideration than the total volume of blood collected.

______ Except for intravascular infections, bacteria usually enter the circulation through the lymphatic system.

______ Almost every known bacterial species and many fungal species have been implicated in extravascular bloodstream infections.

______ Blood drawn for blood culture collection from patients with existing IV lines must be drawn above the existing line.

______ In transient seeding of the blood from a sequestered focus of infection, such as an abscess, bacteria are released in the blood approximately 60 minutes before a febrile episode.

______ Extravascular types of bloodstream infection include infective endocarditis, mycotic aneurysm, and suppurative thrombophlebitis.

______ *S. aureus* is an important cause of septicemia without endocarditis.

______ The increasing use of IV catheters, arterial lines, and vascular prostheses enable normal microbiota of the skin to be a major contributor to bloodstream infections.

______ Most basic blood culture media contain a nutrient broth and 1.2% gelatin.

______ Colonization of intravenous and central catheters by bacteria and fungi are the major nosocomial source of illness and death in bloodstream infection.

11. Matching: *Match each term with the correct description.*

_____ septic shock
_____ occult
_____ neoplasm
_____ fungemia
_____ disseminate
_____ hypoxia
_____ isotonic
_____ hypertonic
_____ transient
_____ vegetation
_____ infective endocarditis
_____ mycotic aneurysm
_____ suppurative thrombophlebitis
_____ septicemia
_____ endotoxins

a. presence of fungi in the blood
b. be carried
c. reduction in oxygen levels
d. infection of the endocardium
e. web of platelets, inflammatory cells, and entrapped organisms
f. inflammation of a vein wall
g. weakening of arterial wall caused by an infection, which then may rupture
h. passing from one place to another
i. hidden
j. serious manifestation of sepsis, causing septic shock, DIC, and major organ failure
k. abnormal mass of cells capable of causing cancer
l. presence of bacteria and their toxins in the blood
m. a substance in the cell walls of gram-negative organisms
n. hyperosmotic; media with added osmotic stabilizers
o. media without osmotic additives

12. Short Answer

(1) Discuss the processes that may lead to the development of infective endocarditis, and name some of the bacteria identified as the primary cause of this medical condition.
(2) Successful recovery of microorganisms from blood cultures is dependent on what factors?
(3) Explain the different ways bacteria may be present in the bloodstream of infected individuals.
(4) What are some of the contributing factors that may predispose a patient to a bloodstream infection?
(5) Explain the difference between exotoxin and endotoxin and how they contribute to the disease process known as septicemia.
(6) What makes molds resistant to the host cell defense mechanisms?
(7) What is a unique consideration microbiologists must face when organisms isolated from blood cultures are bacteria that are generally considered contaminants?
(8) What are the associating factors that allow bacteria to contribute to the development of a neoplasm?
(9) Name some of the viruses responsible for bloodstream infections and describe their pathogenesis.

68

Infections of the Lower Respiratory Tract

OBJECTIVES

1. Define the trachea, bronchi, bronchioles, and alveoli, and explain the anatomic structure of the lower respiratory system.
2. List the most common etiologic agents responsible for lower respiratory disease and pneumonia in patients of various ages and categories: children less than 5 years of age, school-age children, young adults, older adults, and immunocompromised patients.
3. Describe the virulence factors found in bacteria and viruses associated with infection of the lower respiratory tract.
4. List the four possible routes of transmission or dissemination within the body that allow organisms to cause an infection in the lungs.
5. Name the most important decision for physicians regarding the treatment of pneumonia in older individuals and list the three-step process used to guide them in this decision.
6. List the most prevalent cause of community-acquired pneumonia in adults.
7. Differentiate between community-acquired and hospital-acquired (health care–associated) pneumonia.
8. State the factors anaerobic bacteria possess that enhance their ability to produce disease; explain how these anaerobes gain entrance to the lungs.
9. Define Lukens trap and explain the type of patient or specimen associated with the method.
10. Describe the difference between early-onset and late-onset hospital- or ventilator-associated pneumonia.
11. List the primary etiologic agent of lung infections identified in cystic fibrosis patients.
12. Name the organisms most often associated with pneumo-opportunistic infection in HIV-positive individuals.
13. Explain the mechanisms that, because of the bacterial production of toxins, enable microorganisms to produce respiratory-associated disease.
14. Explain how the host immune system can contribute to microorganism growth in the respiratory disease process.
15. Explain why *Mycobacterium tuberculosis* is a classic representative of an intracellular pathogen.
16. Describe specimens collected for respiratory infections, including determination of specimen quality and rejection criteria for the following: sputum, induced sputum, endotracheal suction, pleural fluid, bronchoalveolar lavage, bronchial washing, and bronchial brush sample.
17. Explain how the microbiologist would test for the less common causes of respiratory infection, including *Pneumocystis jiroveci, Legionella* spp., *Chlamydia pneumoniae, Bordetella pertussis, Mycoplasma pneumonia,* and *Nocardia.*

General Considerations

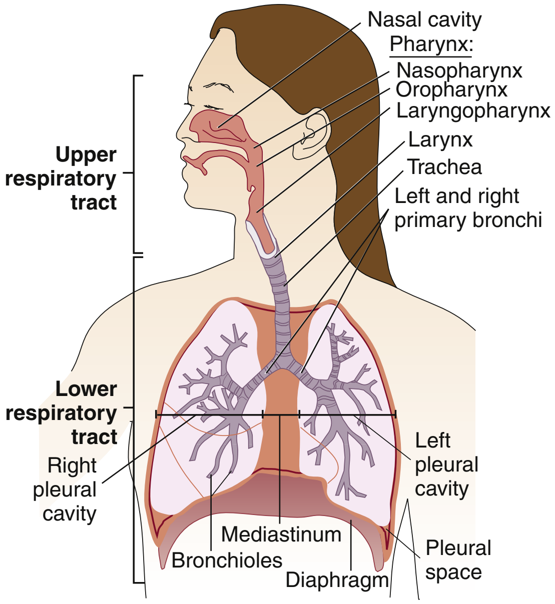
Anatomy

The **respiratory tract** can be divided into two major areas: the **upper respiratory tract** consists of all structures above the larynx, whereas the **lower respiratory tract** follows airflow below the larynx through the trachea to the bronchi and bronchioles and then into the alveolar spaces where gas exchange occurs (Fig. 68.1). The respiratory and gastrointestinal tracts are the two major connections between the interior of the body and the outside environment. The respiratory tract is the pathway through which the body acquires fresh oxygen and removes unneeded carbon dioxide. It begins with the nasal and oral passages, which humidify inspired air, and extends past the nasopharynx and oropharynx to the **trachea** and then into the lungs. The trachea divides into **bronchi,** which subdivide into **bronchioles,** the smallest branches that terminate in the **alveoli.** Some 300 million alveoli are estimated to be present in the lungs; these are the primary microscopic gas exchange structures of the respiratory tract.

Familiarization with the anatomic structure of the thoracic cavity ensures proper specimen collection from various sites in the lower respiratory tract for processing by the laboratory. The **thoracic cavity,** which contains the heart and lungs, has three partitions separated from one another by **pleura** (Fig. 68.1). The lungs occupy the right and left pleural cavities, whereas the **mediastinum** (space between the lungs) is occupied mainly by the esophagus, trachea, large blood vessels, and heart.

Pathogenesis of the Respiratory Tract: Basic Concepts

Microorganisms primarily cause disease by a limited number of pathogenic mechanisms (Chapter 3). Because these mechanisms relate to respiratory tract infections, they are discussed briefly. Encounters between the human body and microorganisms occur many times each day. However, establishment of infection after such contact tends to be the exception rather than the rule. Whether an organism is successful in establishing an infection depends not only on the organism's ability to cause disease (pathogenicity) but also on the human host's ability to prevent the infection.



• **Fig. 68.1** Anatomy of the respiratory tract, including upper and lower respiratory tract regions.

Host Factors

The human host has several mechanisms that nonspecifically protect the respiratory tract from infection that includes the conducting airways and the lower respiratory tract. In the conducting airways these mechanisms include the nasal hairs, convoluted passages, and the mucous lining of the nasal turbinates (long curled bones within nasal cavity); secretory IgA, IgM, IgG, and nonspecific antibacterial substances (lysozyme, lactoferrin, secretory leukocyte proteinase inhibitor) in respiratory secretions; the cilia and mucous lining of the trachea; sharp-angled branching of airways; and reflexes such as coughing, sneezing, and swallowing. These mechanisms prevent foreign objects or organisms from entering the bronchi and gaining access to the lungs, which remain sterile in the healthy host. Aspiration of minor amounts of oropharyngeal material, as occurs often during sleep, plays an important role in the pathogenesis of many types of pneumonia. Once particles escape the mucociliary sweeping activity and enter the alveoli, phagocytes, such as dendritic cells and alveolar macrophages ingest them and carry them to the lymphatics. Additional nonspecific mechanisms of the lower respiratory tract include the chemical nature of the alveolar fluid (surfactant, fibronectin, immunoglobulins, complement, free fatty acids, and iron-binding proteins), and bronchus-associated lymphoid tissue (BALT).

• BOX 68.1 Organisms Present in the Nasopharynx and Oropharynx of Healthy Humans

Possible Pathogens

Acinetobacter spp.
Viridans streptococci, including *Streptococcus anginosus* group
Beta-hemolytic streptococci
Streptococcus pneumoniae
Staphylococcus aureus
Neisseria meningitides
Mycoplasma spp.
Haemophilus influenzae
Haemophilus parainfluenzae
Moraxella catarrhalis
Candida albicans
Herpes simplex virus
Enterobacterales
Mycobacterium spp.
Pseudomonas spp.
Burkholderia cepacia
Filamentous fungi
Klebsiella ozaenae
Eikenella corrodens
Bacteroides spp.
Peptostreptococcus spp.
Actinomyces spp.
Capnocytophaga spp.
Actinobacillus spp., *Actinobacillus actinomycetemcomitans*
Aggregatibacter aphrophilus
Entamoeba gingivalis
Trichomonas tenax

Rare Pathogens

Nonhemolytic streptococci
Micrococci
Corynebacterium spp.
Coagulase-negative staphylococci
Neisseria spp., other than *Neisseria gonorrhoeae* and *Neisseria meningitides*
Lactobacillus spp.
Veillonella spp.
Spirochetes
Rothia dentocariosa
Leptotrichia buccalis
Selenomonas
Wolinella
Rothia mucilaginosus (formerly *Stomatococcus mucilaginosus*)
Campylobacter spp.

In addition to these nonspecific host defenses, normal microbiota of the nasopharynx and oropharynx help prevent colonization by pathogenic organisms of the upper respiratory tract. Normal bacterial microbiota prevents the colonization of pathogens by competing for the same space and nutrients as well as production of **bacteriocins** and metabolic products that are toxic to invading organisms. Some of the bacteria that can be isolated as part of the indigenous human microbiome of healthy hosts, as well as many species that may cause disease under certain circumstances and are often isolated from the respiratory tracts of healthy persons, are listed in Box 68.1. Under certain circumstances and for unknown reasons, these colonizing organisms can cause disease—perhaps because of previous damage by a viral infection, loss of some host immunity, or physical damage to the respiratory epithelium (e.g., from smoking). Differentiation of normal microbiota of the respiratory tract is important for determining the importance of an isolate in the clinical laboratory. Colonization does not always represent an infection. It is important to differentiate colonization from infection based on the specimen source, number of organisms present, and presence or quantity of white blood cells. Organisms isolated from normally sterile sites in the respiratory tract by sterile methods that prevent contamination with normal microbiota should be definitively identified and reported to the clinician.

Microorganism Virulence Factors

Organisms possess traits or produce products that promote colonization and subsequent infection in the host. The **virulence,** or disease-producing capability of an organism, depends on several factors including adherence, production of toxins, amount of growth or proliferation, tissue damage, avoiding the host immune response, and ability to disseminate.

Adherence

For any organism to cause disease, it must first gain a foothold within the respiratory tract to grow to sufficient numbers to produce symptoms. Therefore, most etiologic agents of respiratory tract disease must first adhere to the mucosa of the respiratory tract. The presence of normal microbiota and the overall state of the host affect the ability of microorganisms to adhere. Surviving or growing on host tissue without causing overt harmful effects is termed colonization. Except for those microorganisms inhaled directly into the lungs, all etiologic agents of disease must first colonize the respiratory tract before they can cause harm.

Streptococcus pyogenes possess specific adherence factors such as fimbriae comprising molecules such as lipoteichoic acids and M proteins. These molecules appear as a thin layer of fuzz surrounding the bacteria. *Staphylococcus aureus* and certain viridans streptococci are other bacteria that possess these lipoteichoic acid adherence complexes. Many gram-negative bacteria (which do not have lipoteichoic acids), including Enterobacterales, *Legionella* spp., *Pseudomonas* spp., *Bordetella pertussis,* and *Haemophilus* spp., also adhere by means of proteinaceous fingerlike surface fimbriae. Viruses possess either a hemagglutinin (influenza and parainfluenza viruses) or other proteins that mediate their epithelial attachment.

Toxins

Certain microorganisms are almost always considered to be etiologic agents of disease if they are present in any numbers in the respiratory tract because they possess virulence factors that are expressed in every host. These organisms are listed in Box 68.2. The production of extracellular toxin (exotoxins) was one of the first pathogenic mechanisms discovered among bacteria. *Corynebacterium diphtheria, Corynebacterium ulcerans,* and *Corynebacterium pseudotuberculosis* are classic examples of a bacteria that produce disease through the action of an extracellular toxin. Once the organism colonizes the upper respiratory epithelium, it produces a toxin that is disseminated systemically, adhering preferentially to central nervous system cells and muscle cells of the heart. Systemic disease is characterized by myocarditis, peripheral neuritis, and local disease that can lead to respiratory distress. Growth of toxigenic *Corynebacterium* spp. causes necrosis and sloughing of the epithelial mucosa, producing a “diphtheritic (pseudo) membrane,” which may extend from the anterior nasal mucosa to the bronchi or may be limited to any area between—most often the tonsillar and peritonsillar areas. The membrane may cause sore throat and interfere with respiration and swallowing. Although nontoxic strains of *Corynebacterium* spp. can cause local disease, it is much milder than disease associated with toxigenic strains.

Some strains of *Pseudomonas aeruginosa* produce a toxin similar to diphtheria toxin. Whether this toxin contributes to the pathogenesis of respiratory tract infection with *P. aeruginosa* has not been established. *B. pertussis,* the agent of whooping cough, also produces toxins. The role of these toxins in production of disease is not clear. They may act to inhibit the activity of phagocytic cells or to damage cells of the respiratory tract. *S. aureus* and beta-hemolytic streptococci produce extracellular enzymes capable of damaging host cells or tissues. Extracellular products of staphylococci aid in the production of tissue necrosis and the destruction of phagocytic cells and contribute to the abscess formation associated with infection caused by this organism. Although *S. aureus* can be recovered from throat specimens, it has not been proven to cause pharyngitis. Enzymes of streptococci, including hyaluronidase, allow rapid dissemination of the

• BOX 68.2 Respiratory Tract Pathogens

Definite Respiratory Tract Pathogens

Corynebacterium spp. (toxin-producing)
Mycobacterium tuberculosis
Mycoplasma pneumoniae
Chlamydia trachomatis
Chlamydia pneumoniae
Bordetella pertussis
Legionella spp.
Pneumocystis jiroveci
Nocardia spp.
Histoplasma capsulatum
Coccidioides spp.
Cryptococcus spp. (may also be recovered from patients without disease)
Blastomyces dermatitidis
Viruses (respiratory syncytial virus, coronaviruses, human metapneumovirus, adenoviruses, enteroviruses, hantavirus, herpes simplex virus, influenza and parainfluenza virus, rhinoviruses, severe acute respiratory syndrome)

Rare Respiratory Tract Pathogens

Francisella tularensis
Bacillus anthracis
Yersinia pestis
Burkholderia pseudomallei
Coxiella burnetii
Chlamydia psittaci
Brucella spp.
Salmonella spp.
Pasteurella multocida
Klebsiella rhinoscleromatis
Varicella-zoster virus (VZV)
Parasites

bacteria. Many other etiologic agents of respiratory tract infection also produce extracellular enzymes and toxins.

Microorganism Growth

In addition to adherence and toxin production, pathogens cause disease by merely growing in host tissue, interfering with normal tissue function, and attracting host immune effectors, such as neutrophils and macrophages. Once these cells begin to attack the invading pathogens and repair the damaged host tissue, an expanding reaction ensues with more nonspecific and immunologic factors being attracted to the area, increasing the amount of host tissue damage. Respiratory viral infections usually progress in this manner, as do many types of pneumonias (inflammation and accumulation of fluid in the alveoli), such as those caused by *Streptococcus pneumoniae, S. pyogenes, S. aureus, Haemophilus influenzae, Neisseria meningitidis, Moraxella catarrhalis, Mycoplasma pneumoniae, Mycobacterium tuberculosis,* and most gram-negative bacilli.

Avoiding the Host Response

Another virulence mechanism present in various respiratory tract pathogens is the ability to evade host defense mechanisms. *S. pneumoniae, N. meningitidis, H. influenzae, Klebsiella pneumoniae,* mucoid *P. aeruginosa, Cryptococcus* spp., and others possess polysaccharide capsules that serve both to prevent engulfment by phagocytic host cells and to protect somatic antigens from being exposed to host immunoglobulins. The capsular material is produced in such abundance by certain bacteria, such as pneumococci, that soluble polysaccharide antigen particles can bind host antibodies, blocking them from serving as opsonins. Vaccine consisting of capsular antigens provides host protection to infection, indicating that the capsular polysaccharide is a major virulence mechanism of *H. influenzae, S. pneumoniae,* and *N. meningitidis.*

Some respiratory pathogens evade the host immune system by multiplying within host cells. *Chlamydia trachomatis, Chlamydia psittaci, Chlamydia pneumoniae,* and all viruses replicate within host cells. They have evolved methods for being taken in by the "nonprofessional" phagocytic cells of the host to where they thrive within the intracellular environment. Once within these cells, the organism is protected from host humoral immune factors and other phagocytic cells. This protection lasts until the host cell becomes sufficiently damaged that the organism is then recognized as foreign by the host and is attacked. A second group of organisms that cause respiratory tract disease comprises organisms capable of survival within phagocytic host cells (usually macrophages). Once inside the phagocytic cell, these respiratory tract pathogens can multiply. *Legionella, Pneumocystis jiroveci,* and *Histoplasma capsulatum* are some of the more common intracellular pathogens.

M. tuberculosis is the classic representative of an intracellular pathogen. In primary tuberculosis, the organism is carried to an alveolus in a **droplet nucleus,** a tiny aerosol particle containing tubercle bacilli. Once phagocytized by alveolar macrophages, organisms are carried to the nearest lymph node, usually in the hilar or other mediastinal chains (bronchopulmonary lymph nodes). In the lymph node, the organisms slowly multiply within macrophages. Ultimately, *M. tuberculosis* destroys the macrophage and is subsequently taken up by other phagocytic cells. Tubercle bacilli multiply to a critical mass within the protected environment of the macrophages, which are prevented from accomplishing phagosome-lysosome fusion capable of destroying the bacteria. Having reached a critical mass, the organisms spill out of the destroyed macrophages, through the lymphatics, and into the bloodstream, producing mycobacteremia and carrying tubercle bacilli to many parts of the body. In most cases, the host immune system reacts sufficiently at this point to kill the bacilli; however, a small reservoir of live bacteria may be left in areas of normally high oxygen concentration, such as the apical (top) portion of the lung. These bacilli are walled off, and years later, an insult to the host, either immunologic or physical, may cause breakdown of the focus of latent tubercle bacilli, allowing active multiplication and disease (secondary tuberculosis). In certain patients with primary immune defects, the initial bacteremia seeds bacteria throughout a compromised host, leading to **disseminated** or **miliary tuberculosis.** Growth of the bacteria within host macrophages and histiocytes in the lung causes an influx of more effector cells, including lymphocytes, neutrophils, and histiocytes, eventually resulting in **granuloma** formation, then tissue destruction and cavity formation. The lesion consists of a semisolid, amorphous tissue mass resembling semisoft cheese, from which it received the name **caseating necrosis** (death of cells or tissues). The infection can extend into bronchioles and bronchi from which bacteria are disseminated via respiratory secretions and coughing. Aerosolized droplets are produced by coughing and contain organisms that are inhaled by the next susceptible host. Other portions of the patient's lungs may become infected as well through aspiration (inhalation of a fluid or solid).

Diseases of the Lower Respiratory Tract

Bronchitis

Acute

Acute bronchitis is characterized by acute inflammation of the tracheobronchial tree. This condition may be part of, or preceded by, an upper respiratory tract infection such as influenza (the "flu") or the common cold. Most infections occur during the winter when acute respiratory tract infections are common.

The pathogenesis of acute bronchitis has no specific documented cause but appears to be a mixture of viral cytopathic events and a response by the host immune system. Regardless of the cause, the protective functions of the bronchial epithelium are disturbed, and excessive fluid accumulates in the bronchi. Depending on the source of infection, destruction of the bronchial epithelium may be either extensive (e.g., influenza virus) or minimal (e.g., rhinovirus colds).

TABLE 68.1 Major Causes of Acute Bronchitis

Bacteria	Viruses
Bordetella pertussis, Bordetella parapertussis, Mycoplasma pneumoniae, Chlamydia pneumoniae	Influenza virus, adenovirus, rhinovirus, coronavirus (other less common viruses: respiratory syncytial virus, human metapneumovirus, coxsackie A21 virus)

Clinically, bronchitis is characterized by cough, variable fever, and sputum production. **Sputum** (pus from the lungs) is often clear at the onset but may become **purulent** as the illness persists. Bronchitis may manifest as **croup** (a clinical condition marked by a barking cough or hoarseness).

The value of microbiologic studies to determine the cause of acute bronchitis in otherwise healthy individuals has not been established. Acute bronchitis is often caused by infection with viral agents, such as influenza and respiratory syncytial virus (RSV). Less than 10% of acute bronchitis is caused by bacterial pathogens including *M. pneumoniae, B. pertussis*, and *C. pneumoniae*. The bacterium *B. pertussis* (Chapter 36) is often associated with bronchitis in infants and preschool children (Table 68.1). The best specimen for diagnosis of pertussis is a deep nasopharyngeal specimen; nasopharyngeal aspirates are more sensitive than swabs in younger patients (infants and young children). Swabs should be dacron or rayon.

Chronic Versus Acute

Chronic bronchitis is a common condition affecting about 10% to 25% of adults. This disease is defined by clinical symptoms in which excessive mucus production leads to coughing up sputum on most days during at least 3 consecutive months for more than 2 successive years. Cigarette smoking, infection, and inhalation of dust or fumes are important contributing factors. Acute bronchitis is not related to long-term injury causing damage to the lungs but is typically a result of an infectious process.

Patients with chronic bronchitis can suffer from acute flare-ups of infection, but determination of the cause of the infection is difficult. Potentially pathogenic bacteria, such as nonencapsulated strains of *H. influenzae, S. pneumoniae,* and *M. catarrhalis,* are frequently cultured from the bronchi of these patients. Because of chronic colonization, it is difficult to incriminate one of these organisms as the specific cause of an acute infection in patients with chronic bronchitis. Although the role of bacteria in acute infections in these patients is questionable, viruses are frequent causes.

Bronchiolitis

Bronchiolitis, the inflammation of the smaller diameter bronchiolar epithelial surfaces, is an acute viral lower respiratory tract infection that primarily occurs during the first 2 years of life. Characteristic clinical manifestations include an acute onset of wheezing and hyperinflation as well as cough, rhinorrhea (runny nose), tachypnea (rapid breathing), and respiratory distress. The disease is primarily associated with viral infections including human metapneumovirus and RSV. RSV accounts for 40% to 80% of cases of bronchiolitis and demonstrates a marked seasonality; the etiologic agents of bronchiolitis are listed in Box 68.3. Like other viral infections, bronchiolitis shows a marked seasonality in temperate climates with a yearly increase in cases during winter to early spring.

• BOX 68.3 Viral Agents That Cause Bronchiolitis

Respiratory syncytial virus
Parainfluenza viruses, types 1–3
Rhinoviruses
Adenoviruses
Influenza viruses
Enteroviruses
Human metapneumovirus

Initially, the virus replicates in the epithelium of the upper respiratory tract, but in infants it rapidly spreads to the lower respiratory tract. Early inflammation of the bronchial epithelium progresses to necrosis. Symptoms such as wheezing may be related to the type of inflammatory response to the virus and other host factors. For the most part, patients are managed based on clinical parameters, with the laboratory having a role in cases that require hospitalization; a specific viral cause can be identified in many infants by viral isolation from respiratory secretions, preferably from a nasal wash (Chapter 64).

Pneumonia

Pneumonia (inflammation and accumulation of fluid in the lower respiratory tract involving the lung's airways and supporting structures) is a major cause of illness and death. There are two major categories of pneumonias: those considered community-acquired pneumonia (patients are believed to have acquired their infection outside the hospital setting) and those including hospital- or ventilator-associated (patients are believed to have acquired their infection within hospital setting, usually at least 2 days following admission) or health care–associated (affects only patients hospitalized in an acute care hospital for 2 or more days within 90 days of infection from a long-term care facility; or patients who have received recent intravenous antibiotic therapy, chemotherapy, or wound care within 30 days of the current infection; or who have attended a hospital, hemodialysis clinic, or other outpatient clinic) pneumonia. Nevertheless, once a microorganism has successfully invaded the lung, disease can follow, affecting the alveolar spaces and their supporting structure, the interstitium, and the terminal bronchioles.

Pathogenesis

Organisms can cause infection of the lung by four possible routes: by upper airway colonization or infection that subsequently extends into the lung, by aspiration of organisms (thereby avoiding the upper airway defenses), by inhalation of airborne droplets containing the organism, or by seeding of the lung via the blood from a distant site of infection. Viruses cause primary infections of the respiratory tract and inhibit host defenses that, in turn, can lead to a secondary bacterial infection. For example, viruses may destroy respiratory epithelium and disrupt normal ciliary activity. Presumably, the growth of viruses in host cells disrupts the function of the latter and encourages the influx of nonspecific immune effector cells, exacerbating the damage. Damage to host epithelial tissue by virus infection is known to predispose patients to secondary bacterial infection.

Aspiration of oropharyngeal contents is important in the pathogenesis of many types of pneumonia. Aspiration may occur during a loss of consciousness such as during anesthesia or a seizure, or after alcohol or drug abuse, but other individuals, particularly geriatric patients, may also develop **aspiration pneumonia.** Neurologic disease or esophageal pathology and periodontal disease or gingivitis are other important risk factors. Aided by gravity and often by loss of some host nonspecific protective mechanisms, organisms reach lung tissue, where they multiply and attract host inflammatory cells. Other mechanisms include inhalation of aerosolized material and hematogenous seeding. The buildup of cell debris and fluid contributes to the loss of lung function and thus to the pathology.

Furthermore, regarding the pathogenesis of hospital-associated, health care–associated, and ventilator-associated pneumonias, health care devices, the environment, and the transfer between the patient and staff or other patients can serve as sources of pathogens causing pneumonia. The primary routes for bacterial entry into the lower respiratory tract are by aspiration of oropharyngeal organisms or leakage of secretions containing bacteria around an endotracheal tube. For these reasons, intubation and mechanical ventilation significantly increase the risk of pneumonia (6- to 21-fold). In addition, bacterial and viral biofilm in the endotracheal tube with subsequent spread to distal airways may be important in the pathogenesis of ventilator-associated pneumonia.

Clinical Manifestations

The symptoms suggestive of pneumonia include fever, chills, chest pain, and cough. In the past, pneumonias were classified into two major groups: (1) typical or acute pneumonias (e.g., *S. pneumoniae*) and (2) atypical pneumonias, based on whether the cough was productive or nonproductive of mucoid sputum. However, analysis of symptoms of pneumonia caused by the atypical pneumonia pathogens (*M. pneumoniae, Legionella pneumophila, M. tuberculosis, Francisella tularensis, C. psittaci, Coxiella burnetii,* and *C. pneumoniae*) has revealed no significant differences from those symptoms of patients with typical bacterial pneumonias. Because of this overlap in symptoms, it is important to consider all possible etiologies associated with the patient's clinical presentation.

Some patients with pneumonia exhibit no signs or symptoms related to their respiratory tract (i.e., some only have fever). Therefore, physical examination of the patient, chest radiography, patient history, and clinical laboratory findings are important. In addition to respiratory symptoms, 10% to 30% of patients with pneumonia complain of headache, nausea, vomiting, abdominal pain, diarrhea, and myalgias.

Epidemiology and Etiologic Agents

As previously mentioned, there are two major categories of pneumonias: those considered community-acquired pneumonias and hospital-, ventilator-, or health care–associated pneumonias (HCAPs). Because the epidemiology and causes can differ, these categories are discussed separately. Pneumonia in an immunocompromised patient is addressed separately in this chapter. Emerging viral infections associated with severe acute respiratory syndrome (SARS and COVID-19) and influenza outbreaks (H1N1) are typically associated with upper respiratory infections but may lead to serious lower respiratory infections in young, elderly, or immunocompromised patients. See Chapter 65 for detailed information related to these emerging viral infectious diseases and diagnostic recommendations.

Community-Acquired Pneumonia

Community-acquired pneumonia may be caused by bacteria, fungi, viruses, or protozoans. Because symptoms are often nonspecific, empirical antibiotic therapy is typically administered before the identification of the etiologic agent. The cause of acute pneumonia is strongly dependent on age. More than 80% of the cases of pneumonia in infants and children are caused by viruses, compared with less than 10% to 20% of the cases of pneumonia in adults.

Children. Community-acquired pneumonia in children is a common and potentially serious infection. Determining the cause of pneumonia is challenging because the lungs are rarely sampled directly, and sputum is difficult to obtain from children. Among previously healthy patients 2 months to 5 years old, RSV, human metapneumovirus, parainfluenza, influenza, and adenoviruses are the most common etiologic agents of lower respiratory tract disease. Children are less likely to develop bacterial pneumonia, usually caused by *H. influenzae, S. pneumoniae,* or *S. aureus.* Neonates may acquire lower respiratory tract infections with *C. trachomatis* or *P. jiroveci* (which likely indicates an immature immune system or an underlying immune defect).

M. pneumoniae and *C. pneumoniae* are the most common causes of bacterial pneumonia in school-age children (5 to 14 years of age). The four most common causes of community-acquired viral pneumonia in children include influenza, RSV, parainfluenza, and adenovirus. The agents associated with health care–associated (nosocomial) outbreaks in children include the influenza virus, RSV, and adenovirus. Mixed viral and bacterial infections have been documented in 35% of patients, with most of these (81%) being mixed viral-bacterial infections. In addition, the time of onset of hospital- or ventilator-associated pneumonia is an important epidemiologic variable and risk factor: early-onset pneumonia (defined as occurring within the first 4 days of hospitalization) usually carries a better prognosis, being more likely to be caused by antibiotic-sensitive bacteria, whereas late-onset pneumonia (5 days or more) is more likely to be caused by multidrug-resistant organisms and is associated with increased patient morbidity and mortality.

Young Adults. The most common etiologic agent of lower respiratory tract infection among adults younger than 30 years of age is *M. pneumoniae,* which is transmitted via close contact. Contact with secretions seems to be more important than inhalation of aerosols for transmission and infection. After contact with respiratory mucosa, *Mycoplasma* can adhere to and colonize respiratory mucosal cells. Both a protein adherence factor and gliding motility determine virulence. *Mycoplasma* attach to the cilia of respiratory mucosal cells; once there, they multiply and destroy ciliary function. Attachment and cytotoxins produced by the organisms induce cell damage. *C. pneumoniae* is the third most common agent of lower respiratory tract infection in young adults, following mycoplasmas and influenza viruses; it also affects older individuals. *Chlamydia* spp., intracellular pathogens capable of disrupting cellular function and causing respiratory disease, are similar to viral pathogens.

The epidemiology and treatment of community-acquired and hospital-acquired pneumonia have changed dramatically because of improvements in diagnostics, antimicrobial therapy, and supportive care modalities. The changes in the organization of health care has made the distinction between community-acquired, hospital-acquired, and HCAP less clear. However, pneumonia remains an important cause of morbidity and mortality in elderly patients. The American Thoracic Society and the Infectious Disease Society of America guidelines have suggested that patients who have been hospitalized in the last 90 days, reside in a nursing home or long-term care facility, or have had recent intravenous antibiotic therapy or hemodialysis be classified as a patient with HCAP. Patients with HCAP have a higher incidence of cardiopulmonary and neurodegenerative diseases, cancer, chronic kidney disease, chronic obstructive pulmonary disease, and immunosuppression than elderly patients with community-acquired pneumonia. Both populations become infected with various organisms. The organisms most frequently responsible for community-acquired pneumonia include *S. pneumoniae, H. influenzae, M. pneumoniae, C. pneumoniae, M. catarrhalis,* and *Legionella* spp. The increasing use of the pneumococcal vaccine has decreased the incidence of pneumococcal *(S. pneumoniae)* pneumonia. Factors that contribute to the onset of pneumonia include decreased mucociliary function, cough reflex, level of consciousness, periodontal disease, and general mobility. Patients with health care–associated infections are more frequently colonized with gram-negative bacilli and other multidrug-resistant pathogens, perhaps because of poor oral hygiene, decreased saliva, or decreased epithelial cell turnover. The microorganisms associated with these infections, in addition to those previously mentioned, may include methicillin-resistant *S. aureus* (MRSA), *P. aeruginosa,* a variety of Enterobacterales, *Acinetobacter* spp., anaerobic bacteria, carbapenamase-resistant *Klebsiella pneumoniae,* and extended-spectrum beta-lactamase–resistant Enterobacterales (ESBLS). According to the Infectious Diseases Society of America (IDSA), the decision to hospitalize a patient or to treat him or her as an outpatient is possibly the single most important clinical decision made by physicians during illness. This decision in turn impacts the subsequent site of treatment (home, hospital, or intensive care unit), intensity of laboratory evaluation, antibiotic therapy, and cost. Thus the IDSA has developed management guidelines for community-acquired pneumonia in adults based on a three-step process: (1) assessment of preexisting conditions that might compromise safety of home care, (2) quantification of short-term mortality (referred to as the pneumonia port severity index [PSI] and based on a prediction rule derived from more than 14,000 patients) with subsequent assignment of patients to five risk classes (classes I through V), and (3) clinical judgment. The PSI, however, is not useful for patients in nursing homes or other health care facilities. It is therefore essential to properly assess the severity of the disease in cases of community-acquired and HCAP in elderly patients in a manner that clearly includes the three major management guidelines as outlined by the IDSA.

Pneumonia secondary to aspiration of gastric or oral secretions is common. The most common agents include oral anaerobes such as black-pigmented *Prevotella* and *Porphyromonas* spp., *Prevotella oris, Prevotella buccae, Prevotella disiens, Bacteroides* spp., fusobacteria, and anaerobic or microaerophilic streptococci. The most common aerobic isolates associated with community-acquired aspiration pneumonia are *Streptococcus* spp. and *H. influenzae.* The anaerobic infectious agents possess many factors, such as extracellular enzymes and capsules enhancing their ability to produce disease. It is their presence, however, in an abnormal site within a host producing lowered oxidation-reduction potential secondary to tissue damage that contributes to their pathogenicity. *S. aureus,* various Enterobacterales (*Serratia marcescens, Escherichia coli, Acinetobacter* spp., and *K. pneumoniae*), and *Pseudomonas* may also be acquired by aspiration; *Legionella* spp., *M. catarrhalis, C. pneumoniae,* meningococci, and other agents may also be implicated. Pneumonia is the leading cause of death among patients with health care–associated (nosocomial) infections with as high as 50% mortality among patients in intensive care units. Some of these pneumonias are secondary to sepsis, and some are related to contaminated inhalation therapy equipment, particularly for intubated patients. Hospitalized patients or long-term care patients may experience asymptomatic colonization of the upper airway that results in aspiration of microorganisms into the lower respiratory tract. In addition to those organisms previously listed, these patients are more prone to infections with the multidrug-resistant strains of bacteria (ESBLS and MRSA), including *Providencia stuartii, Morganella morganii, E. coli, Proteus mirabilis, K. pneumoniae, Enterobacter* spp., and *S. aureus.*

Adults (Viral Pneumonia)

Adults contract an estimated 100 million cases annually of community-acquired viral pneumonia caused by influenza, adenovirus, enteroviruses (coxsackieviruses and rhinoviruses), coronaviruses (SARS-CoV-2), human metapneumovirus, parainfluenza, and RSV, particularly during epidemics. Influenza-associated viral pneumonia poses an increased risk for pregnant women of approximately four to nine times greater than that of the general public, with the greatest risk associated with the third trimester. RSV is considered the third most common cause of community-acquired pneumoniae with a higher percentage of the deaths occurring in patients over the age of 65. Similar to RSV, human metapneumovirus has been associated with outbreaks in long-term care facilities. After viral pneumonia, secondary bacterial disease is commonly caused by beta-hemolytic streptococci, *S. aureus, M. catarrhalis, H. influenzae,* and *C. pneumoniae.* Other agents that may be considered depending on the geographic location and clinical presentation are viruses in the hantavirus group, the most common of which is sin nombre virus, as well as SARS-CoV-2 and MERS (Chapter 65).

Of these agents, influenza virus, RSV, SARS-CoV-2, and adenovirus have been implicated in health care–associated outbreaks. The time of onset of hospital-, health care–, or ventilator-associated pneumonia is an important epidemiologic variable and risk factor.

Adults (Fungal Pneumonia)

Unusual causes of acute lower respiratory tract infection in adults include *Actinomyces* and *Nocardia* spp. Other agents may rarely be recovered from sputum and include the agents of plague, tularemia, melioidosis *(Burkholderia pseudomallei), Brucella, Salmonella, Coxiella burnetii* (Q fever), *Bacillus anthracis, Pasteurella multocida,* and certain parasitic agents such as *Paragonimus westermani, Entamoeba histolytica, Ascaris lumbricoides,* and *Strongyloides* spp. (the latter may cause fatal disease in immunosuppressed patients). A high index of suspicion by the clinician is usually a prerequisite to a diagnosis of parasitic pneumonia in the United States. Psittacosis should be ruled out as a cause of acute lower respiratory tract infection in patients who have had recent contact with birds. Among the fungal causes, *H. capsulatum, Blastomyces dermatitidis, Coccidioides immitis, Cryptococcus* spp., and, occasionally, *Aspergillus* spp. may cause acute pneumonia. Therefore, occupational history and any exposure to animals are important in suggesting specific potential infectious agents.

Chronic Lower Respiratory Tract Infections

M. tuberculosis is the most likely etiologic agent of chronic lower respiratory tract infection, but fungal infection and anaerobic pleuropulmonary infection may also run a subacute or chronic course. Mycobacteria other than *M. tuberculosis* may also cause such disease, particularly *Mycobacterium avium* complex and *Mycobacterium kansasii.* Although possible causes of acute, community-acquired lower respiratory tract infections, fungi and parasites are more commonly isolated from patients with chronic disease. *Actinomyces* and *Nocardia* may also be associated with gradual onset of symptoms. *Actinomyces* is usually associated with an infection of the pleura or chest wall, and *Nocardia* may be isolated along with an infection caused by *M. tuberculosis.* The pathogenesis of many of the infections caused by agents of chronic lower respiratory tract disease is characterized by the requirement for breakdown of cell-mediated immunity in the host or the ability of these agents to avoid being destroyed by host cell-mediated immune mechanisms. This may be caused by an effect on macrophages, the ability to mask foreign antigens, sheer size, or some other factor, allowing microbes to grow within host tissues without eliciting an overwhelming local immune reaction.

Cystic fibrosis (CF) is a genetic disorder that leads to persistent bacterial infection in the lung, causing airway wall damage and chronic obstructive lung disease. Eventually, a combination of airway secretions and damage leads to poor gas exchange in the lungs, cardiac malfunction, and subsequent death. Patients with CF may present as young adults with chronic respiratory tract disease or, more commonly, as children with gastrointestinal problems and stunted growth. *S. aureus* is the most prevalent bacterial pathogen. *H. influenzae* is also often identified from the upper airway of young children with CF. A very mucoid *Pseudomonas,* characterized by production of copious amounts of extracellular capsular polysaccharide, can be isolated from the sputum of almost all patients with CF who are older than 18 years of age, becoming more prevalent with increasing age after 5 years. Even if CF has not been diagnosed, isolation of a mucoid *P. aeruginosa* from sputum should alert the clinician to the possibility of underlying disease. Microbiologists should always report this unusual morphologic feature. In addition to mucoid *Pseudomonas* and *S. aureus,* patients with CF are likely to harbor *H. influenzae; S. pneumoniae; Stenotrophomonas maltophilia; Achromobacter xylosoxidans; Ralstonia* spp.; *Cupriavidus* spp.; *Pandoraea* spp.; *E. coli;* strains of *Burkholderia cepacia* complex; fast-growing mycobacteria *(Mycobacterium abscessus)*; RSV; influenza; and fungi including *Aspergillus, Scedosporium* spp., and *Exophiala dermatitidis.* In addition, because of the viscous mucous plugs associated with CF, several anaerobic organisms and normal oral microbiota have been detected in the lungs of CF patients, including *Prevotella, Veillonella, Actinomyces,* and *Fusobacterium. Gemella* and *Rothia mucilaginosa* have been identified and associated with poor outcomes in CF patients. Using advanced diagnostic molecular methods, additional organisms have also been identified in chronic polymicrobial CF infections, including viridans streptococci, *Streptococcus constellatus, Streptococcus milleri, Streptococcus intermedius,* and *Streptococcus anginosus* group.

Lung abscess is usually a complication of acute or chronic pneumonia. In these circumstances, organisms infecting the lung cause localized destruction of the lung parenchyma (functional elements of the lung). Symptoms associated with lung abscess are similar to those of acute and chronic pneumonia, except symptoms fail to resolve with treatment.

Immunocompromised Patients

Patients With Neoplasms. Patients with cancer are at high risk to become infected because of either granulocytopenia or other defects in phagocytic defenses, cellular or humoral immune dysfunction, damage to mucosal surfaces and the skin, and various medical procedures such as blood product transfusion. In these patients, the nature of the malignancy often determines the cause (Table 68.2), and pneumonia is a frequent clinical manifestation.

TABLE 68.2 Examples of Infectious Agents Commonly Associated With Certain Malignancies

Malignancy (Site and Type of Infections)	Pathogens
Acute nonlymphocytic leukemia (pneumonia, oral lesions, cutaneous lesions, urinary tract infections, hepatitis, most often sepsis without obvious focus)	Enterobacterales *Pseudomonas* Staphylococci *Corynebacterium jeikeium* *Candida* *Aspergillus* *Mucor* Hepatitis C and other non-A, non-B
Acute lymphocytic leukemia (pneumonia, cutaneous lesions, pharyngitis, disseminated disease)	Streptococci (all types) *Pneumocystis jiroveci* Herpes simplex virus Cytomegalovirus Varicella-zoster virus
Lymphoma (disseminated disease, pneumonia, urinary tract infections, sepsis, cutaneous lesions)	*Brucella* *Candida* (mucocutaneous) *Cryptococcus* spp. Herpes simplex virus (cutaneous) Varicella-zoster virus Cytomegalovirus *Pneumocystis jiroveci* *Toxoplasma gondii* *Listeria monocytogenes* Mycobacteria *Nocardia* *Salmonella* Staphylococci Enterobacterales *Pseudomonas* *Strongyloides stercoralis*
Multiple myeloma (pneumonia, cutaneous lesions, sepsis)	*Haemophilus influenzae* *Streptococcus pneumoniae* *Neisseria meningitides* Enterobacterales *Pseudomonas* Varicella-zoster virus *Candida* *Aspergillus*

Transplant Recipients. For successful organ transplantation, the recipient's immune system must be suppressed. As a result, these patients are predisposed to infection. Regardless of the type of organ transplant (heart, renal, bone marrow, lung, liver, pancreas), most infections occur within 4 months after transplantation. Major infections can occur within the first month but are usually associated with infections carried over from the pretransplant period. Pulmonary infections are of great importance in this patient population. Some of the most common causes of pneumonia include *S. aureus, S. pneumoniae, H. influenzae, P. jiroveci,* and cytomegalovirus. In addition, other organisms such as *Cryptococcus* spp., *Aspergillus* spp., *Candida* spp., *Nocardia* spp., and others can cause life-threatening pulmonary infection.

Patients With Human Immunodeficiency Virus. Patients who are infected with human immunodeficiency virus (HIV) are at high risk for developing pneumonia. As discussed in the previous chapter, opportunistic infections because of severe immunodeficiency are a major cause of illness and death among these patients. In the United States the most common opportunistic infection among patients with acquired immune deficiency syndrome (AIDS) is *P. jiroveci* pneumonia. Although *P. jiroveci* is a major pulmonary pathogen, other organisms must be considered in this patient population, including *M. tuberculosis* and *M. avium* complex, as well as common bacterial pathogens such as *S. pneumoniae* and *H. influenzae.* In addition to these common pathogens, many other organisms can cause lower respiratory tract infections, including *Nocardia* spp., *Rhodococcus equi* (a gram-positive, aerobic, pleomorphic organism), and *Legionella* spp. Additional opportunistic respiratory infections occur from viral agents such as cytomegalovirus and herpes simplex virus (HSV) (Chapter 65).

Pleural Infections

If an organism infecting the lung subsequently gains access to the pleural space via an abnormal passage (**fistula**), the patient may develop an **empyema** (pus in a body cavity such as the pleural cavity). Symptoms in these patients are insidious, because early during disease they are related to the primary infection in the lung. Once enough purulent exudate is formed, typical physical and radiographic findings indicative of an empyema are produced.

Laboratory Diagnosis of Lower Respiratory Tract Infections

Specimen Collection and Transport

Although rapid determination of the etiologic agent is of paramount importance in managing pneumonia, the responsible pathogen is not identified in as many as 50% of patients, despite extensive diagnostic testing. Unfortunately, no single test can identify all potential lower respiratory tract pathogens. Refer to Table 5.1 for an overview of the methods used to collect, transport, and process specimens from the lower respiratory tract.

Sputum

Expectorated

The examination of expectorated sputum has been the primary means of determining the causes of bacterial pneumonia. However, lower respiratory tract secretions will be contaminated with upper respiratory tract secretions, especially saliva, unless they are collected using an invasive technique. For this reason, sputum is among the least clinically relevant specimens received for culture in microbiology laboratories, even though it is one of the most numerous and time-consuming specimens.

Good sputum samples depend on thorough health care worker education and patient understanding throughout all phases of the collection process. Food should not have been ingested for 1 to 2 hours before expectoration, and the mouth should be rinsed with saline or water just before expectoration. Patients should be instructed to provide a deep-coughed specimen. The material should be expelled into a sterile container, with an attempt to minimize contamination by saliva. Specimens should be transported to the laboratory immediately. Even a moderate amount of time at room temperature can result in the loss of viable infectious agents and the recovery of pathogens.

Induced

Patients unable to produce sputum may be assisted by respiratory therapists, who use postural drainage and thoracic percussion to stimulate production of acceptable sputum. Before specimen collection, patients should brush the buccal mucosa, tongue, and gums with a wet toothbrush. As an alternative, an aerosol-induced specimen may be collected for the isolation of mycobacterial or fungal agents. Induced sputum is also recognized for its high diagnostic yield in cases of *P. jiroveci* pneumonia. Aerosol-induced specimens are collected by allowing the patient to breathe aerosolized droplets, using an ultrasonic nebulizer containing 10% 0.85% NaCl or until a strong cough reflex is initiated. Lower respiratory secretions obtained in this way appear watery, resembling saliva, although they often contain material directly from alveolar spaces. These specimens are usually adequate for culture and should be accepted in the laboratory without prescreening. Obtaining such a specimen may obviate the need for a more invasive procedure, such as bronchoscopy or needle aspiration.

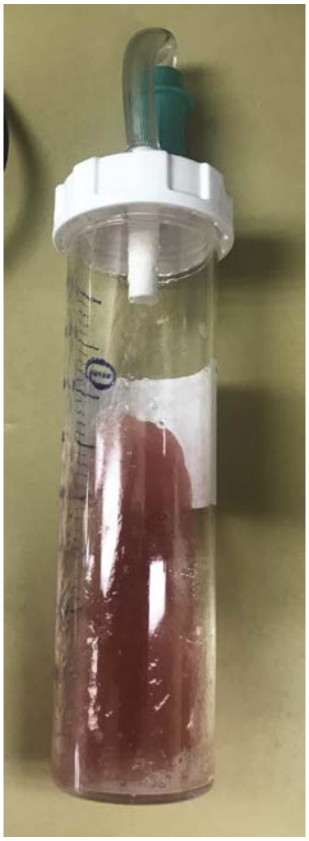
The gastric aspirate is used exclusively for isolation of acid-fast bacilli and may be collected from patients who are unable to produce sputum, particularly young children. Before the patient wakes up in the morning, a nasogastric tube is inserted into the stomach and contents are withdrawn (on the assumption that acid-fast bacilli from the respiratory tract were swallowed during the night and will be present in the stomach). The relative resistance of mycobacteria to acidity allows them to remain viable for a short period. Gastric aspirate specimens must be delivered to the laboratory immediately so that the acidity can be neutralized. Specimens can be neutralized and then transported if immediate delivery is not possible.

Endotracheal or Tracheostomy Suction Specimens

Patients with tracheostomies are unable to produce sputum in the normal fashion, but lower respiratory tract secretions can easily be collected in a Lukens trap (Fig. 68.2). Tracheostomy aspirates or tracheostomy suction specimens should be treated as sputum by the laboratory. Patients with tracheostomies rapidly become colonized with gram-negative bacilli and other nosocomial pathogens. Such colonization per se is not clinically relevant, but these organisms may be aspirated into the lungs and cause pneumonia. Culture results should be correlated with clinical signs and symptoms.

Bronchoscopy

Bronchoscopy specimens include bronchoalveolar lavage (BAL), bronchial washing, bronchial brushing, and transbronchial biopsies. The diagnosis of pneumonia, particularly in HIV-infected and other immunocompromised patients, often necessitates the use of more invasive procedures. Fiberoptic bronchoscopy has dramatically affected the evaluation and management of these infections. With this method, the bronchial mucosa can be directly visualized and collected for biopsy, and the lung tissue can be sent for transbronchial biopsy for the evaluation of lung cancer and other lung diseases. Although transbronchial biopsy is



• **Fig. 68.2** Tracheal secretions received in the laboratory in a Lukens trap.

important, the procedure is often associated with significant complications such as bleeding. The sample should be transported in sterile 0.85% saline.

During bronchoscopy, physicians obtain bronchial washings or aspirates, BAL samples, protected bronchial brush samples, or specimens for transbronchial biopsy. Bronchial washings or aspirates are collected by inserting a small amount of sterile physiologic saline into the bronchial tree and withdrawing the fluid. These specimens will be contaminated with upper respiratory tract microbiota such as viridans streptococci and *Neisseria* spp. Recovery of potentially pathogenic organisms from bronchial washings should be attempted.

A deep sampling of desquamated host cells and secretions can be collected through bronchoscopy and BAL. Lavages are especially suitable for detecting *Pneumocystis* cysts and fungal elements. During this procedure, a high volume of saline (100 to 300 mL) is infused into a lung segment through the bronchoscope to obtain cells and protein of the pulmonary interstitium and alveolar spaces. It is estimated that more than 1 million alveoli are sampled during this process. The value of this technique in conjunction with quantitative culture for the diagnosis of most major respiratory tract pathogens, including bacterial pneumonia, has been documented. Scientists have found significant correlation between acute bacterial pneumonia and greater than 10^3 to 10^4 bacterial colonies per milliliter of BAL fluid. BAL has been shown to be a safe and practical method for diagnosing opportunistic pulmonary infections in immunosuppressed patients. At bedside, nonbronchoscopic "mini BAL" using a Metras catheter has been introduced; typically, 20 mL or less of saline is instilled.

Another type of respiratory specimen is obtained via a protected catheter bronchial brush as part of a bronchoscopy examination. Specimens obtained by this moderately invasive collection procedure are suited for microbiologic studies, particularly in aspiration pneumonia. Protected specimen brush bristles collect from 0.001 to 0.01 mL of material. An overview of the collection process is shown in Fig. 68.3. Upon receipt, contents of the bronchial brush may be suspended in 1 mL of broth solution with vigorous vortexing and inoculated onto culture media using a 0.01-mL calibrated inoculating loop. Some researchers have indicated that specimens obtained via double-lumen–protected catheters are suitable for both anaerobic and aerobic cultures. Colony counts of at least 1000 organisms per milliliter in the broth diluent (or 10^6/mL in the original specimen) have been considered to correlate with infection. All facets of the bronchoscopic procedure—such as order of sampling, use of anesthetic, and rapidity of plating—should be rigorously standardized.

Transtracheal Aspirates

Percutaneous transtracheal aspirates (TTAs) are obtained by inserting a small plastic catheter into the trachea via a needle previously inserted through the skin and cricothyroid membrane. This invasive procedure, although somewhat uncomfortable for the patient and not suitable for all patients (it cannot be used in uncooperative patients, in patients with bleeding tendency, or in patients with poor oxygenation), reduces the likelihood that a specimen will be contaminated by upper respiratory tract microbiota and diluted by added fluids, provided care is taken to keep the catheter from being coughed back up into the pharynx. Although this technique is rarely used, anaerobes, such as *Actinomyces* and those associated with aspiration pneumonia, can be isolated from TTA specimens.

Other Invasive Procedures

When **pleural empyema** is present, thoracentesis may be used to obtain infected fluid for direct examination and culture. This constitutes an excellent specimen that accurately reflects the bacteriology of an associated pneumonia. Laboratory examination of such material is discussed in Chapter 76. Blood cultures, of course, should always be obtained from patients with pneumonia.

For patients with pneumonia, a thin needle aspiration of material from the involved area of the lung may be performed percutaneously. If no material is withdrawn into the syringe after the first try, approximately 3 mL of sterile saline can be injected and then withdrawn into the syringe. Patients with emphysema, uremia, thrombocytopenia, or pulmonary hypertension may be at increased risk of complications (primarily pneumothorax [air in the pleural space] or bleeding) from this procedure. The specimens obtained are very small in volume, and protection from aeration is usually impossible. This technique is more frequently used in children than in adults.

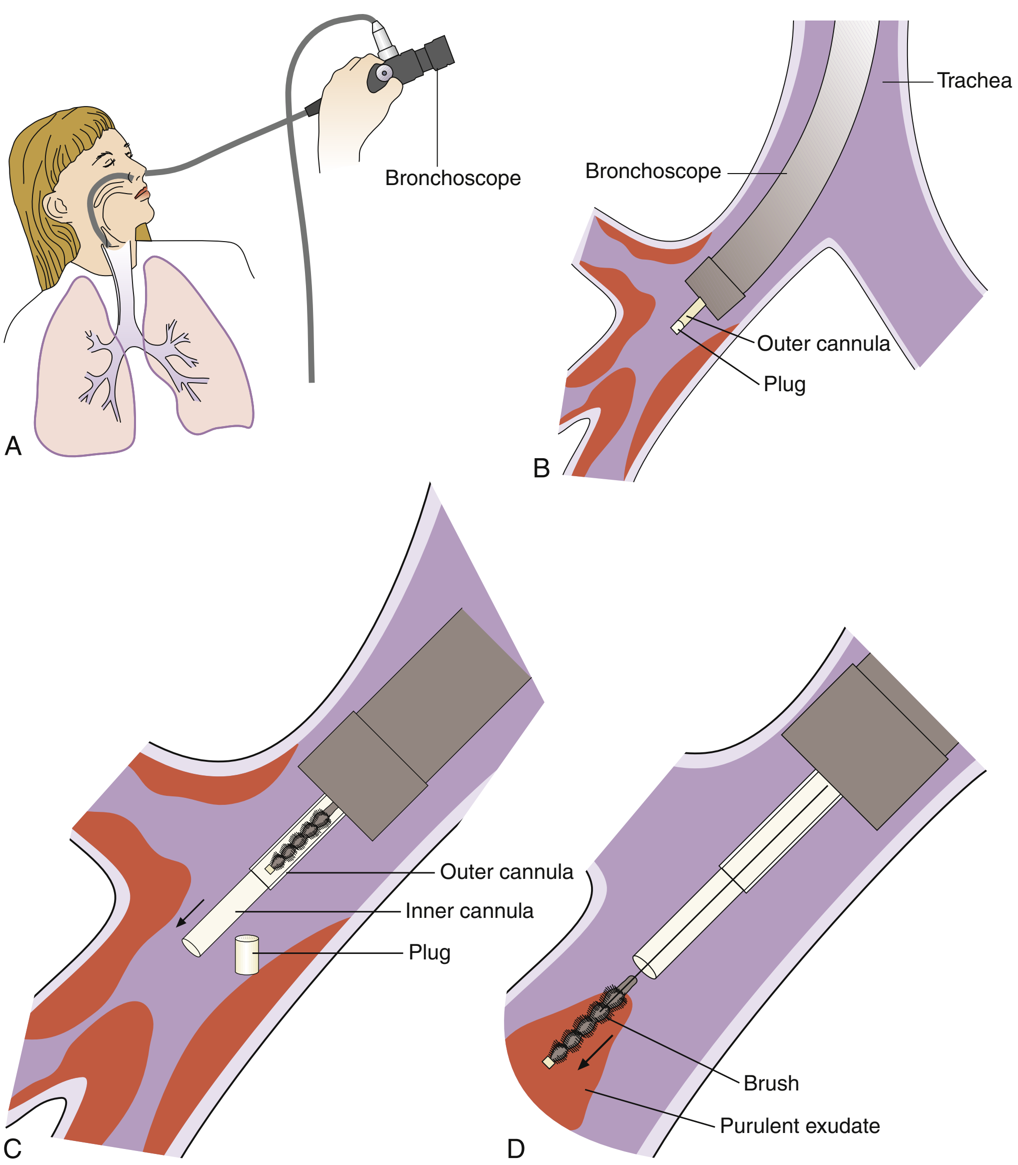
The most invasive procedure for obtaining respiratory tract specimens is the open lung biopsy. Performed by surgeons, this method is used to procure a wedge of lung tissue. Biopsy specimens are extremely helpful for diagnosing severe viral infections, such as herpes simplex pneumonia, for rapid diagnosis of *Pneumocystis* pneumonia, and for other hard-to-diagnose or life-threatening pneumonias.

Specimen Processing

Direct Visual Examination

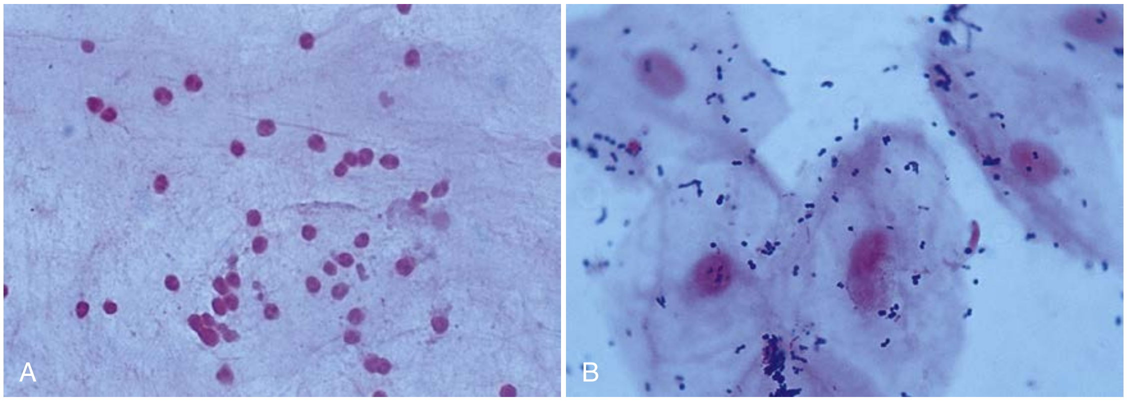
Lower respiratory tract specimens can be examined by direct wet preparation for parasites and special procedures for *Pneumocystis.* Fungal elements can be visualized under phase microscopy with 10% potassium hydroxide, under ultraviolet light with calcofluor white, or using periodic acid-Schiff–stained smears.

For most other evaluations, the specimen must be fixed and stained. Bacteria and yeasts can be recognized on Gram stain. One of the most important uses of the Gram stain, however, is to evaluate the quality of expectorated sputum received for routine bacteriologic culture. A portion of the specimen consisting of purulent material is chosen for the stain. The smear can be evaluated adequately even before it is stained, thus negating the need for Gram stain of specimens later judged unacceptable. An acceptable specimen yields fewer than 10 squamous epithelial cells per low-power field



• **Fig. 68.3** Overview for obtaining a protected catheter bronchial brush during a bronchoscopy examination. (A) The bronchoscope is introduced into the nose and advanced through the nasopharyngeal passage into the trachea. The bronchoscope is then inserted into the lung area of interest. (B) A small brush that holds 0.001 to 0.01 mL of secretions is placed within a double cannula. The end of the outermost tube or cannula is closed with a displaceable plug made of absorbable gel. The cannula is inserted to the proper area. (C) Once in the correct area, the inner cannula is pushed out, dislodging the protective plug as it is extruded. (D) The brush is then extended beyond the inner cannula, and the specimen is collected by "brushing" the involved area. The brush is withdrawn into the inner cannula, which is withdrawn into the outer cannula to prevent contamination by upper airway organisms as it is removed.

(100×). The number of white blood cells may not be relevant, because many patients are severely neutropenic, and specimens from these patients will not show white blood cells on Gram stain examination. On the other hand, the presence of 25 or more polymorphonuclear neutrophils (PMNs) per 100× field, together with few squamous epithelial cells, implies an excellent specimen (Fig. 68.4). Samples that contain predominantly upper respiratory tract material should be rejected. Previously, only expectorated sputa were suitable for rejection based on microscopic screening. However, endotracheal aspirates (ETAs) from mechanically ventilated adult patients can be screened by Gram stain. Criteria used to reject ETAs from adult patients include greater than 10 squamous epithelial cells per low-power field or no organisms seen under oil immersion (1000×). In *Legionella* pneumonia, sputum may be scant and watery, with few or no host cells. Such specimens may be positive by direct fluorescent antibody (DFA) stain and culture, and they should not be subjected to screening procedures. Conversely, sputum from patients with CF should be screened. A throat swab is an acceptable specimen from patients with CF in selected clinical settings and should be processed in a similar



• Fig. 68.4 Gram stain of sputum specimens. (A) This specimen contains numerous polymorphonuclear leukocytes and no visible squamous epithelial cells, indicating that the specimen is acceptable for routine bacteriologic culture. (B) This specimen contains numerous squamous epithelial cells and rare polymorphonuclear leukocytes, indicating an inadequate specimen for routine sputum culture.

manner as CF sputum. Staining of respiratory samples is useful and should be compared with culture results to reveal errors in procedures, specimen collection, and transport or specimen identification.

Respiratory secretions may need to be concentrated before staining. The cytocentrifuge instrument has been used successfully for this purpose, concentrating the cellular material in an easily examined monolayer on a glass slide. As an alternative, specimens are centrifuged, and the sediment is used for visual examinations and cultures. For screening purposes, the presence of **ciliated columnar bronchial epithelial cells, goblet cells,** or pulmonary macrophages in specimens obtained by bronchoscopy or BAL indicates a specimen from the lower respiratory tract.

In addition to the Gram stain, respiratory specimens may be stained for acid-fast bacilli with either the classic Ziehl-Neelsen or the Kinyoun carbolfuchsin stain. Auramine or auramine-rhodamine is also used to detect acid-fast organisms. Because they are fluorescent, these stains are more sensitive than the acid-fast formulas and are preferable for rapid screening. Slides may be restained with the classic stains directly over the fluorochrome stains if all the immersion oil has been removed carefully with xylene. All the acid-fast stains will reveal *Cryptosporidium* spp. if they are present in the respiratory tract, as may occur in immunosuppressed patients. These patients are often at risk of infection with *P. jiroveci.* Although the modified Gomori methenamine silver stain has been traditionally used to recognize *Nocardia, Actinomyces,* fungi, and parasites, it takes approximately 1 hour of the technologist's time to perform, is technically demanding, and is not suitable as an emergency procedure. A rapid stain, toluidine blue O, has been used in many laboratories with some success. Toluidine blue O can be used to stain *Pneumocystis, Nocardia asteroides,* and some fungi. A monoclonal antibody stain is the optimum stain for *Pneumocystis* (Chapter 58) for less invasive specimens such as BAL and induced sputa.

DFA staining has been used to detect *Legionella* spp. in lower respiratory tract specimens. Sputum, pleural fluid, aspirated material, and tissues are all suitable specimens. Because there are so many different serotypes of legionellae, polyclonal antibody reagents and a monoclonal antibody directed against all serotypes of *L. pneumophila* are used. Because of low sensitivity (50% to 75%), DFA results should not be relied on in lieu of culture. Rather, *Legionella* culture, DFA or urinary antigen, and serology should be performed for optimum sensitivity. See Chapter 34 for details regarding detection of *Legionella* spp.

Commercially available DFA reagents are also used to detect antigens of numerous viruses, including herpes simplex, cytomegalovirus, adenovirus, influenza viruses, and RSV (Chapter 64), but have been replaced in most laboratories by direct nucleic acid amplification testing. Commercial suppliers of reagents provide procedure information for each of these tests. Monoclonal and polyclonal fluorescent stains for *C. trachomatis* are available and may be useful for staining respiratory secretions of infants with pneumonia. Several molecular amplification techniques (Chapter 8) for the direct detection of respiratory pathogens have been described. Amplification assays are also available for the direct detection of *M. tuberculosis* on smear-positive specimens (Chapter 42).

Rapid direct detection from respiratory samples is now available using nucleic acid–based methods. The xTAG Respiratory Viral Panel (RVP) (Luminex Corporation, Austin, TX) can be used for the simultaneous detection of influenza (four types), RSV, human metapneumovirus, and adenovirus from nasopharyngeal swabs. In addition, the FilmArray Respiratory Panel (bioMérieux, Durham, NC) can detect upper respiratory tract infections associated with coronavirus (four types), adenovirus, influenza (five types), rhinovirus, parainfluenza virus (four types), enterovirus, human metapneumovirus, RSV, *B. pertussis, M. pneumoniae,* and *C. pneumoniae* in approximately 1 hour directly from patient samples. Smaller molecular panels are also available, such as the real-time multiplex amplification kit for influenza A and B and RSV (Hologic, San Diego, CA). During the COVID-19 (SARS-CoV-2) outbreak in 2020, the

Centers for Disease Control and Prevention (CDC) released an emergency use authorization (EUA) RT-PCR diagnostic panel. The CDC as well as other commercial manufacturers also produced multiple RT-PCR diagnostic panels capable of detecting SARS-CoV-2, influenzae A, and influenzae B. The *illumigene* (Meridian Bioscience, Inc., Cincinnati, OH) manufacturers produce a variety of nucleic acid–based tests that use isothermal loop-mediated amplification. All but the COVID-19 EUA diagnostic tests, the previously mentioned methods are Food and Drug Administration (FDA)-approved. Diagnostic microbiology is rapidly evolving, and the availability of nucleic acid–based testing continues to expand and evolve quickly. The rapid detection of respiratory pathogens using molecular diagnostics has significantly decreased the turnaround time for the diagnosis of infections. High-throughput nucleic acid sequencing can be used to identify most respiratory pathogens in a specimen for diagnosis. However, there are extensive limitations for the implementation of this technology in the clinical laboratory due to computational and bioinformatics needs. It is important when considering the use of a nucleic acid–based assay that the laboratory consider their patient population, including severity of illness, immune status, and transplant histories. In addition, matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) may be used for organism identification depending on the type of organism isolated. See organism-specific chapters for information on MALDI-TOF MS.

Routine Culture

Most of the commonly sought etiologic agents of lower respiratory tract infections are isolated on routine media: 5% sheep blood agar, MacConkey agar for the isolation and differentiation of gram-negative bacilli, and chocolate agar for *Haemophilus* and *Neisseria* spp. Because of contaminating normal oral microbiota, sputum specimens, specimens obtained by bronchial washing and lavage, tracheal aspirates, and tracheostomy or endotracheal tube aspirates are not inoculated to enrichment broth or incubated anaerobically. Only specimens obtained by percutaneous aspiration (including transtracheal aspiration) and protected bronchial brush are suitable for anaerobic culture; the latter must be completed quantitatively for proper interpretation (refer to prior discussion). Transtracheal and percutaneous lung aspiration material may be inoculated to enriched thioglycollate as well as to solid media. For suspected cases of Legionnaires disease, buffered charcoal-yeast extract (BCYE) agar and selective BCYE should be inoculated. Plates should be streaked in four quadrants to provide a basis for objective semiquantitation to define the amount of growth. After 24 to 48 hours of incubation, the numbers and types of colonies are recorded. For *Legionella* cultures, colonies form on the selective agar after 3 to 5 days at 35°C.

Sputum specimens from patients known to have CF should be inoculated to selective agar, such as specific chromogenic agar, for recovery of *S. aureus* and selective horse blood–bacitracin, incubated anaerobically and aerobically, for recovery of *H. influenzae* that may be obscured by the mucoid *Pseudomonas* on routine media. The use of a selective medium for *B. cepacia,* such as PC or OFPBL agars, is also necessary.

For interpretation of culture results on those specimens contaminated by normal oropharyngeal microbiota (e.g., expectorated and induced sputum, bronchial washings), growth of the predominant aerobic and facultative anaerobic bacteria is reported. To ensure optimum culture reporting, conditions must be well defined in terms of an objective grading system for streaked plates. Finally, the clinical significance of culture findings depends not only on standardized and appropriate laboratory methods but also on how specimens are collected and transported, other laboratory data, and the patient's clinical presentation.

Numerous bacterial agents that cause lower respiratory tract infections are not detected by routine bacteriologic culture. Mycobacteria, *Chlamydia, Nocardia, B. pertussis, Legionella,* and *M. pneumoniae* require special procedures for detection; this also applies to viruses and fungi. Optimal recovery for *M. tuberculosis* requires multiple specimens for acid-fast staining, culture, and at least one sample for nucleic acid–based testing as recommended by the Centers for Disease Control and Prevention. Refer to the appropriate chapter section for more information regarding these organisms. Finally, one must keep in mind those potential agents for bioterrorist attack, such as *B. anthracis, F. tularensis,* and *Yersinia pestis,* that might be recovered from respiratory specimens (Chapter 79).

CASE STUDY 68.1

A 16-month-old boy was admitted with fever, lethargy, and trouble breathing. A diagnosis of pneumonia was made by physical examination. The child had recently been to Panama and was treated with ceftriaxone for cough and fever. His fever continued, despite treatment. On admission, he was given erythromycin therapy. Tracheal aspirate and blood cultures were obtained, but the respiratory specimen contained numerous epithelial cells and yielded normal respiratory flora on culture. A pleural aspirate and blood cultures were positive for *Streptococcus pneumoniae,* which was resistant to erythromycin and penicillin and intermediate in susceptibility to ceftriaxone. The patient was given high doses of ceftriaxone and vancomycin and responded to this therapy.

Questions

1. What criteria are used in laboratories to reject sputum and tracheal aspirates for culture?
2. If more than 10 squamous epithelial cells per low-power field are seen in a Gram stain but the smear also has numerous white blood cells (more than 25 per low-power field), should the specimen be rejected for culture?
3. In the cases of pneumonia, how many are successfully diagnosed?
4. The organism was reported as resistant to penicillin (MIC of 4 μg/mL) and intermediate in susceptibility to third-generation cephalosporins (minimum inhibitory concentration to ceftriaxone of 2 μg/mL). How does the laboratory test for this organism?

Chapter Review

1. Which of the following lung conditions are a major cause of illness and death?
- **a.** Pneumonia
- **b.** Bronchiolitis
- **c.** Acute bronchitis
- **d.** Chronic bronchitis

2. What is the most common cause of community-acquired pneumonia in adults?
- **a.** *Streptococcus pyogenes*
- **b.** *Streptococcus pneumoniae*
- **c.** *Mycoplasma pneumoniae*
- **d.** *Klebsiella pneumoniae*

3. Psittacosis is a lower respiratory infection in humans caused by contact with what animal?
- **a.** Swine
- **b.** Seals
- **c.** Cats
- **d.** Birds

4. What organism may be recovered as a subacute illness in respiratory disease caused by *M. tuberculosis*?
- **a.** *Nocardia*
- **b.** *Actinomyces*
- **c.** *M. kansasii*
- **d.** *M. avium intracellulare*

5. All the acid-fast stains will reveal which of the following organisms from respiratory specimens?
- **a.** *Mycobacterium tuberculosis*
- **b.** *Mycobacterium avium* complex
- **c.** *Cryptosporidium*
- **d.** All the above

6. Which of the following stains is used to detect *Legionella* in lower respiratory specimens?
- **a.** DFA staining
- **b.** Gram stain
- **c.** Kinyoun carbol fuchsin
- **d.** Ziehl-Neelsen

7. Which of the following media is used in addition to normal respiratory culture media in suspected cases of Legionnaires disease?
- **a.** BCYE
- **b.** Regan-Lowe agar
- **c.** Bordet-Gengou agar
- **d.** Cystine-tellurite agar

8. Which of the following organisms could potentially be isolated from a respiratory specimen and is *not* also considered a potential agent for bioterrorism?
- **a.** *Bacillus anthracis*
- **b.** *Bordetella pertussis*
- **c.** *Francisella tularensis*
- **d.** *Yersinia pestis*

9. Which of the following procedures has dramatically affected the evaluation and management of pneumonia, particularly in HIV-infected and immunocompromised patients?
- **a.** Tracheostomy suction
- **b.** Fiberoptic bronchoscopy
- **c.** Thoracic percussion
- **d.** Catheter bronchial brush

10. True or False

_____ An acceptable sputum specimen when visualized by Gram stain must show significant white blood cells and fewer than 10 squamous epithelial cells per low-power field.

_____ Respiratory specimens first stained for acid-fast bacilli, with auramine or auramine-rhodamine, can be restained with the classic stains directly over the fluorochrome stain if all the immersion oil has been removed with xylene.

_____ A single culture can identify all potential pathogens that cause lower respiratory tract infections.

_____ Sputum is the most clinically relevant specimen received for culture in the microbiology laboratory for the diagnosis of respiratory infection.

______ A moderate amount of time at room temperature will not affect the quality of a sputum sample.

______ Patients with tracheostomies are unable to produce sputum in the normal fashion.

______ The modified Gomori methenamine silver stain has been used traditionally to recognize *Nocardia, Actinomyces,* fungi, and parasites but is technically and time demanding.

______ Pneumonia patients that are assessed to be risk classes II and III generally require hospitalization.

______ The production of extracellular toxin was one of the first pathogenic mechanisms discovered in bacteria.

______ The areas of the lungs most affected by pneumonia are the alveolar spaces and the interstitium, the supporting structure of the alveoli, and the terminal bronchioles.

11. Matching: *Match each term with the correct description.*

______ bronchioalveolar lavage (BAL)
______ catheter bronchial brush
______ percutaneous TTAs
______ aerosol-induced sputum
______ gastric aspirate
______ thoracentesis
______ open lung biopsy

a. needle puncture of the pleural cavity used to obtain pleural fluid for direct examination and culture in patients with pleural empyema
b. used exclusively for isolation of acid-fast bacilli and particularly used for young children
c. used to obtain a wedge of lung tissue to diagnose severe viral infection or other hard-to-diagnose or life-threatening pneumonia
d. good method for detecting *Pneumocystis* cysts and fungal elements
e. useful for detecting anaerobes such as *Actinomyces* but rarely still used
f. useful for isolating agents of mycobacterial or fungal disease; provides a high diagnostic yield in cases of *P. jiroveci* pneumonia
g. good for microbiology studies, particularly in aspiration pneumonia

12. Matching: *Match each term with the correct description.*

______ empyema
______ fistula
______ HAP
______ VAP
______ fimbriae
______ caseating necrosis
______ miliary tuberculosis
______ expectorated
______ alveoli
______ tachypnea
______ rhinorrhea
______ aspiration
______ thoracic cavity
______ mediastinum
______ nosocomial

a. runny nose
b. rapid breathing
c. abnormal passage
d. proteinaceous fingerlike surface structures that help bacteria adhere to host tissue
e. mass of dead tissue resembling soft cheese
f. inhalation of a fluid or solid
g. hospital-acquired pneumonia
h. microscopic structures for gas exchange
i. body space that contains the heart and lungs
j. ventilator-acquired pneumonia
k. pus in a body cavity
l. space between the lungs
m. disseminated disease
n. infection acquired while in the hospital
o. cough up, spit out

13. Short Answer

(1) Explain the benefits of using a *S. pneumoniae* urinary antigen test for presumptive diagnosis of pneumococcal pneumonia.

(2) Why are enrichment broths or anaerobe plates not used in the culture of routine sputum specimens, specimens obtained by bronchial washing, and lavage tracheal aspirates?

(3) What specimens are suited for anaerobic culture with regard to respiratory culture?

(4) What characteristics do the following bacteria share that enable the organisms to resist engulfment by phagocytic host cells: *S. pneumoniae, N. meningitides, H. influenzae, K. pneumoniae, P. aeruginosa,* and *Cryptococcus* spp.?

(5) Define the pathogenesis of acute bronchitis.

(6) When is thoracentesis used to obtain a sample for direct examination and culture?

(7) What is an important epidemiologic variable and risk factor in hospital- or ventilator-associated pneumonia?

(8) What virus infection effect may predispose patients to a secondary bacterial infection?

(9) What hinders diagnosing the causative agent in pediatric pneumonia in children younger than 5 years of age?

69

Upper Respiratory Tract Infections and Other Infections of the Oral Cavity and Neck

OBJECTIVES

1. Explain the anatomy and structures of the upper respiratory tract, including the three parts of the pharynx.
2. Identify the principal causative organism of pharyngitis; name other organisms capable of causing pharyngitis.
3. Define the following conditions: laryngitis, epiglottis, and parotitis. List the etiologic organisms associated with these conditions.
4. Explain the pathogenic mechanisms (virulence factors) associated with *Streptococcus pyogenes* pharyngitis.
5. Define Vincent angina and peritonsillar abscesses. What organism do they share as the causative agent of disease?
6. Describe the disease process caused by pharyngeal infection with *Corynebacterium diphtheriae*; name the hallmark symptom of this infection and list the complications associated with infection.
7. Differentiate between stomatitis and thrush and explain the testing process for each disease.
8. Outline the steps used in the culture of specimens for the isolation of *S. pyogenes*.
9. Explain the signs and symptoms and pathogenic mechanisms associated with disease caused by *Bordetella pertussis*. What special requirements are needed to detect this organism in culture?
10. List three types of periodontal infections that require culture to identify the causative agent of infection; name the bacteria associated with these infections.
11. Explain the unique characteristics of group C and G streptococci and explain how they contribute to their pathogenesis.

General Considerations

Anatomy

The respiratory tract is generally divided into two regions, the upper and the lower.

The upper respiratory tract includes all the structures down to the larynx: the sinuses, throat, nasal cavity, epiglottis, and larynx; the throat is also called the **pharynx.** These anatomic structures are shown in Fig. 69.1.

The pharynx is a tubelike structure that extends from the base of the skull to the esophagus (Fig. 69.1). Made of muscle, this structure is divided into three parts:

- **Nasopharynx**—portion of the pharynx above the soft palate
- **Oropharynx**—portion of the pharynx between the soft palate and epiglottis
- **Laryngopharynx**—portion of the pharynx below the epiglottis that opens into the larynx

The oropharynx and nasopharynx are lined with stratified squamous epithelial cells that are teeming with normal microbiota. The tonsils are contained within the oropharynx; the larynx is located between the root of the tongue and the upper end of the trachea.

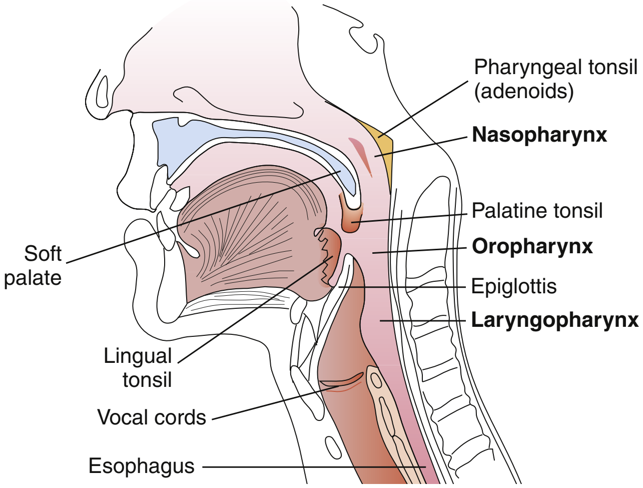
Pathogenesis

An overview of the pathogenesis of respiratory tract infections is presented in Chapter 68. It is important to keep in mind that upper respiratory tract infections may spread and become more serious because the mucosa (mucous membrane) of the upper tract is continuous with the mucosal lining of the sinuses, eustachian tube, middle ear, and lower respiratory tract.

Diseases of the Upper Respiratory Tract, Oral Cavity, and Neck

Upper Respiratory Tract

Diseases of the upper respiratory tract are named according to the anatomic sites involved. Most of these infections are self-limiting, and most infections are of viral origin.



• **Fig. 69.1** The pharynx, including its three divisions and nearby structures.

Laryngitis

Acute laryngitis is usually associated with the common cold or influenza syndromes. Characteristically, patients complain of hoarseness and lowering or deepening of the voice. Acute laryngitis is generally a benign illness.

Acute laryngitis is almost exclusively associated with viral infection. All the major respiratory viruses have been associated with laryngitis; however influenza and parainfluenza viruses, rhinoviruses, adenoviruses, coronavirus, and human metapneumovirus are the most common etiologic agents. If examination of the larynx reveals an exudate or membrane on the pharyngeal or laryngeal mucosa, streptococcal infection, mononucleosis, or diphtheria should be suspected (see the discussion about miscellaneous infections caused by other agents, presented later in this chapter). *Haemophilus influenzae* is the most frequent microorganism recovered from patients with bacterial laryngitis. Chronic laryngitis, although less commonly associated with infectious agents, may be caused by bacteria or fungal isolates. Infections have been identified that are associated with methicillin-resistant *Staphylococcus aureus* (MRSA), *Bordetella pertussis, Mycoplasma pneumoniae,* and *Candida* spp.

Laryngotracheobronchitis

Another clinical syndrome closely related to laryngitis is acute **laryngotracheobronchitis,** or **croup.** Croup is a relatively common illness in young children, primarily those younger than 3 years of age. Of significance, croup can represent a potentially more serious disease if the infection extends downward from the larynx to involve the trachea or even the bronchi. Illness is characterized by variable fever; inspiratory stridor (difficulty in moving enough air through the larynx); hoarseness; and a harsh, barking, nonproductive cough. These symptoms last for 3 to 4 days, although the cough may persist for a longer period. In young infants, severe respiratory distress and fever are common symptoms.

Similar to the etiologic agents of laryngitis, viruses are a primary cause of croup; parainfluenza viruses are the major etiologic agents. In addition to parainfluenza viruses, influenza viruses, respiratory syncytial virus, and adenoviruses can also cause croup.

Other agents capable of causing croup, though not as frequently, include *M. pneumoniae,* rhinoviruses, and enteroviruses.

Epiglottitis

Epiglottitis is an infection of the epiglottis (elastic cartilage flap covering the entrance to the trachea) and other soft tissues above the vocal cords. Infection of the epiglottis can lead to significant edema (swelling) and inflammation resulting in respiratory distress or failure. Infected individuals typically present with fever, difficulty in swallowing because of pain, drooling, and respiratory obstruction with inspiratory stridor. Epiglottitis is a potentially life-threatening disease, because the patient's airway can become completely obstructed (blocked) if not treated.

In contrast to laryngitis, epiglottitis is usually associated with bacterial infections. In the past, 2- to 4-year-old children were typically infected with *H. influenzae* type b as the primary cause of epiglottitis. However, because of the common use of *H. influenzae* type b conjugated vaccine, the typical patient is now an adult that presents with a sore throat. Other organisms implicated are *Streptococcus pneumoniae, Streptococcus pyogenes, Staphylococcus aureus,* and *Neisseria meningitidis*. Diagnosis is established on clinical grounds, including the visualization of the epiglottis, which appears swollen and bright red in color. Bacteriologic culture of the epiglottis is contraindicated because swabbing of the epiglottis may lead to respiratory obstruction. Additional bacterial pathogens identified in cases of epiglottitis include *H. parainfluenzae, Klebsiella pneumoniae,* and *Pseudomonas aeruginosa.* Immunocompromised patients and patients receiving immunosuppressive therapy or antibiotics may experience epiglottitis caused by *Candida* spp. Viral agents including herpes simplex virus type 1 (HSV-1), influenzae B, and parainfluenzae type 3 may cause epiglottitis infection.

Pharyngitis, Tonsillitis, and Peritonsillar Abscesses

Pharyngitis and Tonsillitis

Pharyngitis (sore throat) and **tonsillitis** are common upper respiratory tract infections that affect both children and adults. Acute pharyngitis is an illness that commonly causes people to seek medical care.

Clinical Manifestations. Infection of the pharynx is associated with pharyngeal pain. Visualization of the pharynx reveals erythematous (red) and swollen tissue. Depending on the infectious agent, either inflammatory exudate (fluid with protein, inflammatory cells, and cellular debris), vesicles (small, blisterlike sacs containing liquid) and mucosal ulceration, or nasopharyngeal lymphoid hyperplasia (swollen lymph nodes) may be observed.

Pathogenesis. Pathogenic mechanisms differ and depend on the organism causing the pharyngitis. For example, some organisms directly invade the pharyngeal mucosa (e.g., *Arcanobacterium haemolyticum*), others elaborate toxins and other virulence factors at the site (e.g., *Corynebacterium diphtheriae*), and still others invade the pharyngeal mucosa and elaborate toxins and other virulence factors (e.g., *S. pyogenes*). Pathogenic mechanisms are reviewed in Part III according to various organism groups. Many cases of acute pharyngitis are associated with viral infections, are self-limiting, and require no medical treatment.

Epidemiology and Etiologic Agents. Most cases of pharyngitis occur during the colder months (winter to early spring) and often accompany other infections, primarily those caused by viruses. Patients with respiratory tract infections caused by influenza types A and B, parainfluenza, coxsackie A, rhinoviruses, or coronaviruses typically complain of a sore throat. Pharyngitis, often with ulceration, is also commonly found in patients with infectious mononucleosis caused by either Epstein-Barr virus (EBV) or cytomegalovirus (CMV). Although less common, pharyngitis caused by adenovirus or HSV is clinically severe and results in extensive destruction of the mucosal lining (cytopathology) of the pharynx. Finally, acute retroviral syndrome caused by human immunodeficiency virus 1 (HIV-1) may be associated with acute pharyngitis.

Although different bacteria can cause pharyngitis or tonsillitis, the primary cause of bacterial pharyngitis is *S. pyogenes* (or group A beta-hemolytic streptococci). Viral pharyngitis and pharyngitis or tonsillitis caused by other agents must be differentiated from that caused by *S. pyogenes*. Pharyngitis resulting from *S. pyogenes* is treatable with penicillin and a variety of other antimicrobials, whereas viral infections are not. In addition, treatment is of importance, because infection with *S. pyogenes* can lead to complications such as **acute rheumatic fever** and **glomerulonephritis.** These complications are referred to as **poststreptococcal sequelae** (diseases that follow a streptococcal infection) and are primarily immunologically mediated; these sequelae are discussed in greater detail in Chapter 14. *S. pyogenes* may also cause pyogenic infections (suppurations) of the tonsils, sinuses, and middle ear, or cellulitis as secondary pyogenic sequelae after an episode of pharyngitis. Accordingly, streptococcal pharyngitis is usually treated to prevent both the suppurative (pus forming) and nonsuppurative sequelae, as well as to decrease morbidity.

Although bacteria other than group A streptococci may cause pharyngitis, this occurs less often. Large colony isolates primarily of groups C and G streptococci (classified as *Streptococcus dysgalactiae* subsp. *equisimilis*) are pyogenic streptococci with similar virulence traits as *S. pyogenes;* symptoms of pharyngitis caused by these agents are also similar to *S. pyogenes.* These agents have been associated with poststreptococcal sequelae, namely glomerulonephritis and rheumatic fever. In addition, glomerulonephritis has been reported after infection with *S. equi* subsp. *zooepidemicus.* Studies have demonstrated that these streptococci can exchange genetic information with *S. pyogenes* and thus potentially obtain virulence factors usually associated with *S. pyogenes* such as M proteins, streptolysin O, and superantigen genes. *A. haemolyticum* is also a cause of pharyngitis among adolescents. Examples of agents that can cause pharyngitis or tonsillitis are listed in Table 69.1.

TABLE 69.1 **Examples of Bacteria That Can Cause Acute Pharyngitis and Tonsillitis**

Organism	Disease
Streptococcus pyogenes	Pharyngitis/tonsillitis/ rheumatic fever/scarlet fever
Group C and G beta-hemolytic streptococci	Pharyngitis/tonsillitis
Arcanobacterium haemolyticum	Pharyngitis/tonsillitis/rash
Fusobacterium necrophorum	Pharyngitis/tonsillitis
Neisseria gonorrhoeae	Pharyngitis/tonsillitis/ disseminated disease
Corynebacterium ulcerans	Pharyngitis
Mycoplasma pneumoniae	Pneumonia/bronchitis/ pharyngitis
Yersinia enterocolitica	Pharyngitis/enterocolitis
Human immunodeficiency virus-1	Pharyngitis/acute retroviral disease

Although *H. influenzae, S. aureus,* and *S. pneumoniae* are commonly isolated from nasopharyngeal and throat cultures, they have not been shown to cause pharyngitis. Carriage of any of these organisms, as well as *N. meningitidis,* may have clinical importance for some patients. Cultures of specimens obtained from the anterior nares often yield *S. aureus.* The carriage rate for this organism is especially high among health care workers, and 10% to 30% of the general population can be colonized with this microbe, depending on the population characteristics. Bacterial pharyngitis may also be attributed to infection with *C. diphtheriae, Fusobacterium necrophorum,* and *Neisseria gonorrhoeae.* Viral pharyngitis may be caused by adenoviruses, coronaviruses, EBV, HIV, and influenza.

Vincent angina, also called **acute necrotizing ulcerative gingivitis,** or **trench mouth,** is a mixed bacterial-spirochetal infection of the gingival edge. The infection is relatively rare today, but it is considered a serious disease because it is often complicated by septic jugular thrombophlebitis, bacteremia, and widespread metastatic infection. Adults are affected more commonly than children; poor oral hygiene is a predisposing factor. Multiple anaerobes, especially *F. necrophorum,* are implicated in this syndrome. Although Gram stain of a throat specimen is usually not predictive, in those patients with symptoms suggestive of Vincent angina, Gram stain reveals numerous fusiform, gram-negative bacilli and spirochetes.

• BOX 69.1 Viral Agents That Can Cause Rhinitis

Rhinoviruses	>156 types
Coronaviruses	5 types
Adenoviruses	57 types
Parainfluenza and influenza viruses	5 and 3 types
Respiratory syncytial virus	2 types
Metapneumovirus	2 types
Other viruses: Bocavirus and Enterovirus	

Peritonsillar Abscesses

Peritonsillar abscesses are generally considered a complication of tonsillitis. This infection is most common in children older than 5 years of age and in young adults. It is important to treat these infections, because they can spread to adjacent tissues, as well as erode into the carotid artery to cause an acute hemorrhage. The predominant organisms isolated in peritonsillar abscesses include non–spore-forming anaerobes, such as *Fusobacterium* (especially *F. necrophorum*), *Bacteroides* (including the *Bacteroides fragilis* group), and anaerobic cocci. *S. pyogenes* and viridans streptococci may also be involved.

Rhinitis

Rhinitis (common cold) is an inflammation of the nasal mucous membrane or lining. Depending on the host response and the etiologic agent, rhinitis is characterized by variable fever, increased mucous secretions, inflammatory edema of the nasal mucosa, sneezing, and watery eyes. With rare exceptions, rhinitis is typically associated with viral infections (20% to 25%); some of these agents are listed in Box 69.1. Rhinitis is common because of the large number of different causative viruses, and reinfections may occur. Bacterial agents associated with rhinitis (10% to 15%) include *Chlamydia pneumoniae, M. pneumoniae,* and group A streptococci.

Miscellaneous Infections Caused by Other Agents

Corynebacterium diphtheriae

Pharyngitis caused by *C. diphtheriae* is less common than streptococcal pharyngitis. After an incubation period of 2 to 4 days, diphtheria usually presents as pharyngitis or tonsillitis. Patients are often febrile and complain of sore throat and malaise (body discomfort). The hallmark for diphtheria is the presence of an exudate or membrane that is usually on the tonsils or pharyngeal wall. The gray-white membrane is a result of the action of diphtheria toxin on the epithelium at the site of infection. Complications are common with diphtheria and are usually seen during the last stage of the disease (paroxysmal stage). The most feared complications are those involving the central nervous system, such as seizures, coma, or blindness. Information as to how this organism causes disease is discussed in Chapter 68. Additional specifics regarding this organism are provided in Chapter 16.

Bordetella pertussis

Although mass immunization programs have greatly reduced the incidence of pertussis, substantial numbers of cases (because of outbreaks and regional epidemics) still occur. An increase in the number of identifiable cases may be a result of improved awareness and diagnostic methods, such as nucleic acid–based testing. In addition, the lack of vaccinations of young children has also caused an increase in infections. It is important for laboratories to be capable of detecting, isolating, and identifying the organism either by culture or nucleic acid–based methods, or the specimen should be referred to a reference laboratory.

Characteristically, pertussis, or whooping cough, is a prolonged disease (lasting as long as 6 to 8 weeks) marked by paroxysmal (sudden or intense) coughing.

After an incubation period of 7 to 13 days, a patient with symptomatic infection develops upper respiratory symptoms, including a dry cough, fever, runny nose, and sneezing. After about 2 weeks, this may progress to spells of paroxysmal coughing. As these episodes worsen, the characteristic whoop, caused by attempted inspiration through an epiglottis undergoing spasm, begins. Vomiting may occur, and usually a lymphocytosis is present. This phase of the illness may last as long as 6 weeks. Bacterial culture for *B. pertussis* is effective using nasopharyngeal specimens during the first 2 weeks when symptoms are evident. Amplification and polymerase chain reaction (PCR) may demonstrate positive results within 4 weeks of the onset of symptoms. However, positive results should be interpreted with caution and in correlation with patient signs and symptoms. More information regarding *B. pertussis* is provided in Chapter 36.

Klebsiella spp.

Rhinoscleroma is a rare form of chronic granulomatous infection of the nasal passages, including the sinuses and occasionally the pharynx and larynx. Associated with *Klebsiella rhinoscleromatis,* the disease is characterized by nasal obstruction appearing over a long period, caused by tumorlike growth with local extension. *Klebsiella ozaenae* causes another uncommon condition called **atrophic rhinitis (ozena),** characterized by a chronic, mucopurulent nasal discharge that is often foul smelling. It is caused by secondary, low-grade anaerobic infection.

These two tissue-destructive diseases are transmitted person-to-person through exposure to infected nasal secretions and occur more frequently in tropical climates.

Oral Cavity

Stomatitis

Stomatitis is an inflammation of the mucous membranes of the oral cavity. HSV is the primary agent of this disease, in which multiple ulcerative lesions are seen on the oral mucosa. These lesions are painful and can be found in the mouth and in the oropharynx. Herpetic infections of the oral cavity are prevalent among immunosuppressed patients. Stomatitis has also been associated with *Kingella kingae,* treponemes, and infection with the measles virus.

Thrush

Candida spp. can also invade the oral mucosa. Immunosuppressed patients, including very young infants, may develop oral candidiasis, called **thrush.** Oral thrush can extend to produce pharyngitis or esophagitis, a common finding in patients with acquired immunodeficiency syndrome and in other immunosuppressed patients. Thrush is suspected if whitish patches of exudate on an area of inflammation are observed on the buccal mucosa, tongue, or oropharynx. Oral mucositis or pharyngitis in a granulocytopenic patient may be caused by Enterobacterales, *S. aureus,* or *Candida* spp. and is manifested by erythema, sore throat, and possibly exudate or ulceration. Although typically considered nonpathogenic, the yeast *Saccharomyces cerevisiae* has been reported to cause thrush.

Periodontal Infections

The three dental problems that may require culture and identification in a clinical laboratory include (1) root canal infections, with or without periapical abscess; (2) orofacial odontogenic infections, with or without osteomyelitis (inflammation of a bone) in the jaw; and (3) perimandibular space infections. Oral bacteria are clearly important in other dental processes, such as caries (destruction of the mineralized tissues of the tooth; a cavity), periodontal (tissues in, around, and supporting the tooth) disease, and localized juvenile periodontitis, but clinical laboratories are not involved in culturing in such cases.

Etiologic Agents

The bacteriology is similar in all these infections and involves primarily anaerobic bacteria and streptococci except for perimandibular space infections, which may also involve staphylococci and *Eikenella corrodens.* The streptococci are microaerobic or facultative and are usually alpha-hemolytic (particularly the *Streptococcus anginosus* group—see Chapter 13); they are found in 20% to 30% of dental infections.

Members of the *B. fragilis* group are found in root canal infections, orofacial odontogenic infections, and bacteremia secondary to dental extraction. Anaerobic cocci (both *Peptostreptococcus* and *Veillonella*), pigmented *Prevotella* and *Porphyromonas,* the *Prevotella oralis* group, and *Fusobacterium* are also associated with each of the three conditions mentioned, as well as in postextraction bacteremia. Infection with *Actinomyces israelii* may complicate oral surgery.

Salivary Gland Infections

Acute suppurative parotitis (inflammation of the salivary glands located under the cheek in front of and below the external ear) is seen in very ill patients, especially those who are dehydrated, malnourished, elderly, or recovering from surgery. It is associated with painful, tender swelling of the parotid gland; purulent drainage may be evident at the opening of the duct of the gland in the mouth. *S. aureus* is the major pathogen, but on occasion Enterobacterales, other gram-negative bacilli, and oral anaerobes may play a role in infection. Chronic bacterial parotitis has been described involving *S. aureus* or mixed oral aerobes and anaerobes. Less often, other salivary glands may be involved with a bacterial infection, usually because of ductal obstruction.

The mumps virus is traditionally the major viral agent involved in parotitis; however, since the advent of childhood vaccination, infection with mumps virus is rarely diagnosed. Influenza virus and enteroviruses may also cause this syndrome. Viral parotitis is typically diagnosed using serology. Infrequently, *Mycobacterium tuberculosis* may involve the parotid gland in conjunction with pulmonary tuberculosis.

Neck

Infections of the deep spaces of the neck are potentially serious, because they may spread to critical structures such as major vessels of the neck or to the mediastinum, leading to mediastinitis, purulent pericarditis, and pleural empyema. Oral microbiota is commonly responsible for these types of infections. Accordingly, the predominant organisms are anaerobes, primarily *Peptostreptococcus,* various *Bacteroides, Prevotella, Porphyromonas, Fusobacterium* spp., and *Actinomyces.* Streptococci, chiefly of the viridans variety, are also important. *S. aureus* and various aerobic, gram-negative bacilli may be recovered, particularly from patients developing these problems in the hospital.

Scrofula is a tuberculous infection in the cervical lymph nodes that may be associated with *Mycobacterium scrofulaceum* or *Mycobacterium avium* complex. *Mycobacterium avium* complex is a heterogenous group comprising *M. avium* and *Mycobacterium intracellulare* (Chapter 42). The characteristic signs and symptoms include painless swelling of the lymph nodes with the rare appearance of fever or ulcerations. Diagnosis may require bacterial culture of the lymph nodes, computed tomography (CT) of the neck, biopsy, and chest x-ray.

Diagnosis of Upper Respiratory Tract Infections

Collection and Transport of Specimens

Sterile, dacron, or rayon swabs with plastic shafts are suitable for collecting most upper respiratory tract microorganisms. Flocked swabs may also be used when available. If the swab remains moist, no further precautions need to be taken for specimens cultured within 4 hours of collection. After that period, transport medium is required to maintain viability and prevent overgrowth of contaminating organisms. Swabs for detection of group A streptococci *(S. pyogenes)* are the only exception. This organism is highly resistant to desiccation and remains viable on a dry swab for as long as 48 to 72 hours. Throat swabs are also adequate for recovery of adenoviruses and herpes viruses, *C. diphtheriae, Mycoplasma, Chlamydia,* and *Candida* spp. Transport media is required for the isolation of *Mycoplasma* and *Chlamydia* to ensure viability. Recovery of *C. diphtheriae* is enhanced by culturing both the throat and nasopharynx.

Nasopharyngeal swabs are better suited for recovery of *B. pertussis; Neisseria* spp.; and several viruses, including respiratory syncytial virus, parainfluenza virus, and the other viruses causing rhinitis. Optimum conditions for the collection and transport of specimens for viral detection or culture are described in Chapter 64. Although swabs made of calcium alginate are commonly used to collect nasopharyngeal specimens (excluding those specimens for chlamydia or viral culture), nasopharyngeal secretions collected by either aspiration or washing will improve recovery for *Bordetella* spp., because a larger amount of material is obtained.

The type of swab used for collection is very important. For example, cotton swabs should never be used for culture, because fibers contain fatty acids on the surface, which are capable of killing *Bordetella.* Calcium alginate or dacron swabs are acceptable for obtaining nasopharyngeal swab specimens; calcium alginate is optimal for culture. However, if nucleic acid–based testing is to be performed, dacron or rayon swabs on plastic shafts are preferred. Specimens for culture of *B. pertussis* ideally should be inoculated directly to fresh media at the patient's bedside. If this is not possible, transport for less than 2 hours in 1% casamino acid medium at room temperature is acceptable. If specimens are plated on the day of collection, Amie's transport medium with charcoal is acceptable. If specimens are plated more than 24 hours after collection, Regan-Lowe or Jones-Kendrick transport medium is optimal; both contain charcoal, starch, and nutrients as well as cephalexin. If lengthy delays in transport are expected, transport of specimens in Regan-Lowe medium at 4°C is recommended.

Direct Visual Examination or Detection

A Gram stain of material obtained from upper respiratory secretions or lesions may not improve diagnosis. Yeastlike cells can be identified, which are helpful in identifying thrush, and the characteristic pattern of fusiform and spirochetes of Vincent angina may be visualized. Gram crystal violet (allowed to remain on the slide for 1 minute before rinsing with tap water) and the Gram stain can be used to identify the spirilla and fusiform bacilli of Vincent angina. However, if crystal violet is used, the smear should be very thin, because everything will be intensely gram positive, making a thick smear difficult to read. Additionally, spirilla and bacilli may be stained using a dilute solution of carbol fuchsin.

For causes of pharyngitis, Gram stains are unreliable. Direct smears of exudate from membranelike lesions used to differentiate diphtheria from other causes are also not reliable or recommended.

Fungal elements, including yeast cells and pseudohyphae, may be visualized with a 10% potassium hydroxide (KOH) preparation, calcofluor white fluorescent stain, or periodic acid-Schiff (PAS) stain. Numerous studies have demonstrated that nucleic acid–based amplification tests (NAAT) for *B. pertussis* in nasopharyngeal secretions are superior to culture. A wide variety of commercial systems are available for the detection of *B. pertussis* nucleic acid. Various methods, including fluorescent antibody stain reagents, enzyme immunoassays (EIAs), and NAAT, are also commercially available to detect numerous viral agents (Chapter 64).

Improvement in the development of rapid methods for detecting group A streptococcal antigen or nucleic acid has obviated the need for culture of pharyngeal specimens. At least 40 commercial products are available to identify group A streptococcal antigens using membrane EIA or latex agglutination techniques. Although the specific procedures vary with the EIA kit, several generalizations can be made. Throat swabs are incubated in an acid reagent or enzyme to extract the group A–specific carbohydrate antigen. Dacron swabs seem to be most efficient at releasing antigen, although other types of swabs may yield acceptable results. In laboratory comparisons between a rapid antigen detection method and conventional culture methods for detecting the presence of group A streptococci in throat swabs, the commercial kits have shown relatively acceptable (62% to more than 90%) sensitivity and specificity. Specimens with a negative direct antigen test for group A streptococci should be cultured (requires collection of specimen with two swabs) or confirmed using a nucleic acid method. Group A streptococci can be directly detected from pharyngeal specimens by nucleic acid–based testing using different molecular assay formats. The commercially available assay (Group A Strep Direct Test [GAS Direct], Hologic Inc., Bedford, MA) uses a nonisotopic, chemiluminescent, single-stranded deoxyribonucleic acid (DNA) probe complementary to the ribosomal ribonucleic acid (rRNA) target of the group A streptococcus. The assay detects organisms directly from swab specimens by lysing the bacterial cells before amplification. Dacron swabs are acceptable for use with this assay. Sensitivities of the Hologic GAS Direct test range from 91.7% to 99.3% compared with culture. A rapid-cycle real-time PCR method, the Light Cycler Strep-A (Roche Applied Science, Indianapolis, IN), also detects *S. pyogenes* directly from throat swabs. Using this technology, 32 samples (including controls) can be tested per run in about 1.5 hours. Isothermal DNA amplification is also available for the detection of group A streptococcus from throat swabs (Illumigene Group A Streptococcus, Meridian Bioscience, Inc., Cincinnati, OH) and demonstrates sensitivity equal to the GAS. See Chapter 8 for more information on isothermal DNA amplification.

Culture

Streptococcus pyogenes (Beta-Hemolytic Group A Streptococci)

Because the primary cause of bacterial pharyngitis in North America is *S. pyogenes,* most laboratories routinely screen throat cultures for this organism. Throat culture

TABLE 69.2 **Medium and Atmosphere for Incubation of Cultures to Recover Group A Streptococci From Pharyngeal Specimens**

Media	Atmosphere of Incubation
Sheep blood agar	Anaerobic
Sheep blood agar with coverslip over the primary area of inoculation	Aerobic
Sheep blood agar with trimethoprim-sulfamethoxazole	5%–10% CO_2 or anaerobic

has historically been considered the gold standard for the diagnosis of *S. pyogenes.* Group A streptococci are usually beta-hemolytic; less than 1% are nonhemolytic. Three variables must be taken into consideration regarding successful culture of group A streptococci from pharyngeal specimens: medium, atmosphere, and duration of incubation. There are four recommended combinations of media and atmosphere of incubation for throat specimens; these are listed in Table 69.2. Regardless of the medium and atmosphere of incubation used, culture plates should be incubated for at least 48 hours before reporting as negative for group A streptococci.

Drawbacks to culture include an extended incubation time of 24 to 48 hours for visible colony formation with additional manipulations of the beta-hemolytic organisms for definitive identification (Chapter 14). If sufficient numbers of pure colonies are not available for identification, a subculture requiring additional incubation is necessary. By placing a 0.04-unit differential bacitracin filter paper disk, available commercially, directly on the area of initial inoculation, presumptive identification of *S. pyogenes* can be made after overnight incubation (all of group A and a very small percentage of group B streptococci are susceptible). However, use of the bacitracin disk in the primary area of inoculation reduces the sensitivity and specificity of culture and identification of *S. pyogenes.* Sometimes growth of too few beta-hemolytic colonies or overgrowth of other organisms makes interpretation difficult. Therefore using the bacitracin disk as the only method of identification of *S. pyogenes* is not recommended. New selective agars, such as streptococcal selective agar, have been developed that suppress the growth of almost all normal microbiota and beta-hemolytic streptococci except for groups A and B and *A. haemolyticum.* Direct antigen or nucleic acid detection tests or the PYR test (Chapter 12) can also be carried out on isolated beta-hemolytic colonies.

Corynebacterium diphtheriae

If diphtheria is suspected, the physician must communicate this information to the clinical laboratory. Because streptococcal pharyngitis is included in the differential diagnosis of diphtheria and because dual infections do occur, cultures for *C. diphtheriae* should be plated onto sheep blood agar or streptococcal selective agar, as well as onto special media for recovery of this agent. These special media include a Loeffler agar slant and a cystine-tellurite agar plate. Chapter 16 discusses the identification of the organism. Recovery of this organism is improved when culturing specimens from the throat and nasopharynx of potentially infected patients. In addition to culture, rapid toxigenicity assays, including immunoassays and NAAT, may be used to assist in the diagnosis. Caution should be used when interpreting molecular assays, because positive results have been associated with related species of corynebacteria.

Bordetella pertussis

Freshly prepared Bordet-Gengou agar was the first medium developed for isolation of *B. pertussis* or *B. parapertussis.* However, because it was inconvenient to use, other media were subsequently developed (Chapter 36). Regan-Lowe or charcoal horse blood agar is now recommended for use in diagnostic laboratories. Because the organisms are extremely delicate, specimens should be plated directly onto media, if possible. The yield of positive isolations from clinical cases of pertussis seems to vary from 20% to 98% depending on the stage of disease, previous treatment of the patient, age of the patient, and laboratory techniques. Because of the limitations associated with culture and serologic diagnostic methods, significant effort has been put into developing nucleic acid amplification methods. Nucleic acid–based diagnostic tests for the direct detection of *B. pertussis* and *B. parapertussis* genes by various PCR procedures, including real-time PCR, have replaced direct fluorescent antibody methods (DFA) in the clinical laboratory.

Neisseria spp.

Specimens received in the laboratory for isolation of *N. meningitidis* (for detection of carriers) or *N. gonorrhoeae* should be plated to a selective medium, either modified Thayer-Martin or Martin-Lewis agar. After 24 to 48 hours of incubation in 5% to 10% carbon dioxide, typical colonies of *Neisseria* spp. may be visible. Nucleic acid–based methods have replaced enzyme-linked immunosorbent assay systems for rapid diagnosis of *N. gonorrhoeae* and *N. meningitidis* (Chapter 39).

Epiglottitis

Clinical specimens from cases of epiglottitis (swabs obtained by a physician) should be plated to sheep blood agar, chocolate agar (for recovery of *Haemophilus* spp.), and a streptococcal selective medium. Refer to Table 5.1 for an overview of the methods used to collect, transport, and process different specimens from the upper respiratory tract.

Diagnosis of Infections in the Oral Cavity and Neck

Collection and Transport

It is important to prevent or minimize contamination with oral microbiota when collecting oral and dental material for diagnosis of infection. For collection of material from root canal infection, the tooth is isolated by means of a rubber dam. A sterile field is established, the tooth is swabbed with 70% alcohol, and after the root canal is exposed, a sterile paper point is inserted, removed, and placed into semisolid, nonnutritive, anaerobic transport medium. Alternatively, needle aspiration can be used if sufficient purulent material is present. Completely defining the microbiota of such infections is beyond the scope of routine clinical microbiology laboratories.

Specimens from neck space infections can usually be obtained with a syringe and needle or by biopsy during a surgical procedure. Transport must be under anaerobic conditions.

Direct Visual Examination

All material submitted for culture should be smeared and examined by Gram stain and other appropriate techniques for fungi (i.e., calcofluor white, KOH, or PAS stains), if requested.

Culture

Infections such as peritonsillar abscesses, oral and dental infections, and neck space infections usually involve anaerobic bacteria. The anaerobes involved typically originate in the oral cavity and are often more delicate than anaerobes isolated from other clinical material. Very careful methods are required to provide optimal specimens for anaerobic cultivation, as well as collection and transport for the recovery and identification of the etiologic agents. See Chapter 40 for more information related to anaerobic organisms.

CASE STUDY 69.1

A 2-year-old girl presented to her physician with a sore throat and fever. On examination, her tonsils were enlarged and inflamed. A rapid test was performed for group A streptococci; the test result was negative. The physician decided to treat with amoxicillin regardless of the test results and asked that a culture be performed. The next day the laboratory reported that moderate growth of beta-hemolytic group A streptococcus was present.

Questions

1. List the manual biochemical tests that rapidly identify group A streptococci (*Streptococcus pyogenes*).
2. Not all group A streptococci are *S. pyogenes*. What manual test can be used to differentiate the nonpathogenic group A streptococci from the pathogenic strains?
3. Not all *S. pyogenes* are beta-hemolytic. What is the reason for this phenomenon, and how can the laboratory ensure detection of the nonhemolytic strains?
4. What is the sensitivity of rapid diagnostic tests to detect group A streptococcal antigen?

Chapter Review

1. What is the hallmark physical manifestation for infections with *C. diphtheriae*?
   - **a.** Malaise
   - **b.** Presence of an exudate or membrane on the tonsils or pharyngeal wall
   - **c.** Presence of white vesicles on the tonsils or pharyngeal wall
   - **d.** Edema and inflammation of the tonsils and pharyngeal wall
2. What is the primary cause of stomatitis, inflammation of the mucous membranes of the oral cavity?
   - **a.** HSV
   - **b.** *Klebsiella* spp.
   - **c.** *Candida* spp.
   - **d.** Enterobacterales
3. What is the primary etiologic agent of epiglottitis?
   - **a.** *H. influenzae* type b
   - **b.** *C. diphtheriae*
   - **c.** *S. pyogenes*
   - **d.** *S. aureus*
4. Peritonsillar abscesses are caused by all the following bacteria, *except:*
   - **a.** *Fusobacterium*
   - **b.** *Bacteroides*
   - **c.** Anaerobic cocci
   - **d.** *S. pneumoniae*
5. Oral thrush is a disease often found in what population of patients?
   - **a.** Adults older than 65 years
   - **b.** Young adults 18 to 24 years of age
   - **c.** Immunocompromised patients
   - **d.** Children younger than 12 years
6. What virus traditionally causes viral parotitis?
   - **a.** Influenza virus
   - **b.** Parainfluenza virus
   - **c.** Rhinovirus
   - **d.** Mumps virus
7. Which of the following organisms is highly resistant to desiccation and remains viable on a dry swab for as long as 48 to 72 hours?
   - **a.** *C. diphtheriae*
   - **b.** *B. pertussis*
   - **c.** *S. pyogenes*
   - **d.** *H. influenzae* type b
8. Which of the following swabs *cannot* be used for respiratory specimens intended for viral testing?
   - **a.** Cotton swabs
   - **b.** Dacron swabs
   - **c.** Calcium alginate swabs
   - **d.** Rayon swabs
9. Loeffler agar slant is a special culture medium used to recover which organism?
   - **a.** *S. pyogenes*
   - **b.** *C. diphtheriae*
   - **c.** *B. pertussis*
   - **d.** *N. meningitidis*
10. **True or False**

_____ Gram stains of material collected from upper respiratory secretions or lesions can serve as a valuable tool when used to determine the cause of pharyngitis.

_____ Cotton swabs should always be used for the culture of *B. pertussis,* because the fibers contain fatty acids on the surface, which enhance the growth of *Bordetella* in culture.

_____ Swabs collected from the upper respiratory tract, if they remain moist, do not need to be put in transport medium when cultured within 4 hours of collection.

_____ Pharyngitis caused by adenovirus or HSV is usually less severe than pharyngitis caused by other viruses.

_____ If a child presents with a red swollen epiglottis, the epiglottis should be swabbed to determine the etiologic agent.

_____ Studies have demonstrated that group C and group G streptococci can exchange genetic information with *S. pyogenes* and potentially obtain virulence factors normally associated with *S. pyogenes.*

11. Matching: *Match each term with the correct description.*

______ Vincent angina
______ parotitis
______ inflammatory exudates
______ poststreptococcal sequelae
______ malaise
______ paroxysmal
______ inspiratory stridor
______ rhinoscleroma
______ ozena
______ osteomyelitis

a. inflammation of bone
b. granulomatous infection of the nasal passages
c. difficulty in moving air through the larynx
d. sudden/intense
e. acute necrotizing ulcerative gingivitis
f. swollen salivary glands
g. diseases that follow a streptococcal infection
h. foul-smelling mucopurulent nasal discharge
i. fluid filled with protein
j. body discomfort

12. Short Answer

(1) What complications can arise from an untreated case of pharyngitis caused by *S. pyogenes*? What is the general term used to describe these complications?

(2) Explain what causes the production of the gray, white membrane on the pharyngeal wall in patients infected with *C. diphtheriae.*

(3) What produces the "whoop" in the cough of individuals infected with *B. pertussis*?

70

Meningitis and Other Infections of the Central Nervous System

OBJECTIVES

1. Describe the anatomy of the central nervous system (CNS), and list the anatomic structures that compose it.
2. Define meninges; name the three separate layers and describe their function.
3. Define the cerebrospinal fluid and list its functions.
4. Describe the routes of infection for the CNS.
5. Explain the host defense mechanisms that protect the central nervous system from infection.
6. Define meningitis, and describe the two major types of meningitis, including the etiologic agents.
7. Discuss the cause of acute meningitis, and explain the host predisposing factors for neonates; identify the most commonly associated bacterial pathogens.
8. Discuss how the advent of the *Haemophilus influenzae* type b (Hib) vaccine in the United States has helped to prevent pediatric cases of meningitis.
9. Compare acute and chronic meningitis; outline the distinguishing symptoms and cerebrospinal fluid (CSF) findings for each, including cell counts and chemistry laboratory results.
10. Explain the disease processes for encephalitis and meningoencephalitis.
11. Discuss two ways that meningoencephalitis infections, brain abscesses, or other CNS infections are caused by parasites; identify the associated infecting organisms and the population of patients at increased risk for developing these conditions.
12. Explain the collection, transport, and specimen storage requirements for CSF; include specimen processing and the appropriate distribution of specimen throughout the laboratory.
13. List the culture media used to identify the causative agent of meningitis in bacterial, mycobacterial, and fungal infections; what incubation conditions are required for each type of organism?
14. Describe the use of advanced technologies including matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS), and nucleic acid–based testing in the direct diagnosis of CNS infections.

General Considerations

Anatomy

Diagnosis of an infection involving the central nervous system (CNS) is of critical importance. Most clinicians consider infection in the CNS to be a medical emergency. An understanding of the basic anatomy and physiology of the CNS is helpful for the microbiologist to ensure appropriate specimen processing and interpretation of laboratory results.

Coverings and Spaces of the Central Nervous System

The central nervous system consists of the brain and the spinal cord. Because of the vital and essential role of the CNS in the body's regulatory processes, the brain and spinal cord have two protective coverings: an outer covering consisting of bone and an inner covering of membranes called the **meninges.** The outer bone covering encases the brain (i.e., cranial bones or skull) and spinal cord (i.e., the vertebrae). The meninges are a collective term for the three distinct membrane layers surrounding the brain and spinal column:

- **Dura mater**—outermost membrane layer
- **Arachnoid mater**—middle layer
- **Pia mater**—innermost membrane layer

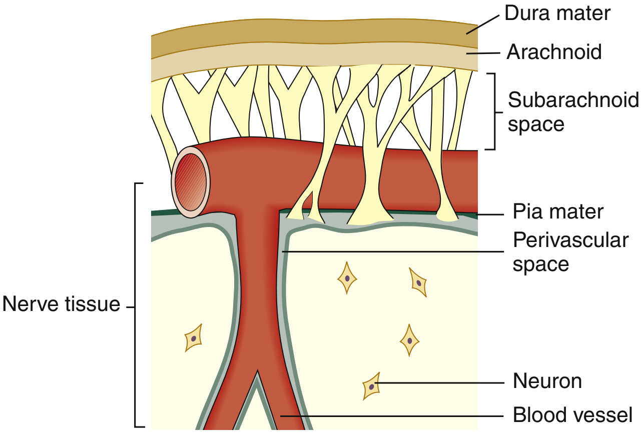
The pia mater and the arachnoid membrane are collectively called the **leptomeninges.** The portion of the arachnoid that covers the top of the brain contains arachnoid villi, which are special structures that absorb the spinal fluid and allow it to pass into the blood.

Between and around the meninges are spaces that include the **epidural, subdural,** and **subarachnoid spaces.** The relative location of the meninges and spaces to one another in the brain are depicted in Fig. 70.1. The location and nature of the meninges and spaces are summarized in Table 70.1.

Cerebrospinal Fluid

Cerebrospinal fluid (CSF) surrounds the brain and spinal cord and has several functions. The CSF provides cushioning and buoyancy for the bulk of the brain, reducing the effective weight of the brain by a factor of 30. CSF carries essential metabolites into the neural tissue and cleanses the tissues of wastes as it circulates around the brain, ventricles, and spinal cord. Every 3 to 4 hours, the entire volume of CSF is exchanged. The amount of CSF in humans depends on the developmental age of the individual, reaching a volume of approximately 150 mL by 5 years of age. In addition to these functions, CSF provides a means by which the brain monitors changes in the internal environment.

CSF is found in the subarachnoid space (Table 70.1) and within cavities and canals of the brain and spinal cord. There are four large, fluid-filled spaces within the brain referred to as **ventricles.** Specialized secretory cells, called the **choroid plexus,** produce CSF. The choroid plexus is located centrally within the brain in the third and fourth ventricles. Approximately 23 mL of CSF are contained within these ventricles in an adult. The fluid travels around the outside areas of the brain within the subarachnoid space, driven primarily by the pressure produced initially at the choroid plexus (Fig. 70.2). By virtue of its circulation, chemical and cellular changes in the CSF may provide valuable information about infections within the subarachnoid space.



• **Fig. 70.1** Cross-section of the brain showing the important membrane coverings and spacing and other key structures.

Routes of Infection

One of the most important defense mechanisms of the CNS is the **blood-brain barrier.** The blood-brain barrier functions to maintain homeostasis in the brain by restricting the flow of chemical constituents from the blood to the CNS. For the CNS to become infected with a bacterium, parasite, or virus, the blood-brain barrier must be penetrated.

Organisms may gain access to the CNS through several primary routes:

- Hematogenous spread: This is followed by entry into the subarachnoid space through the choroid plexus or through other blood vessels of the brain. This is the most common route of infection for the CNS.
- Direct spread from an infected site: The extension of an infection close to or contiguous with the CNS can occasionally occur; examples of such infections include otitis media (infection of middle ear), sinusitis, and mastoiditis.
- Anatomic defects in CNS structures: Anatomic defects as a result of surgery, trauma, or congenital abnormalities can allow microorganisms easy and ready access to the CNS.
- Travel along nerves leading to the brain (direct intraneural): This is the least common route of CNS infection and occurs with organisms such as rabies virus, which travels along peripheral sensory nerves, and herpes simplex virus.

Diseases of the Central Nervous System

Meningitis

Infection within the subarachnoid space or throughout the leptomeninges is called **meningitis.** Based on the host's response to the invading microorganism, meningitis is divided into two major categories: purulent and aseptic meningitis.

TABLE 70.1 Inner Coverings (Meninges) of the Brain, Spinal Cord, and Surrounding Spaces

Anatomic Structure	Relative Location	Key Features
Epidural space	Outside the dura mater yet inside the skull	Cushion of fat and connective tissues
Dura mater	Outermost membrane	Membrane that adheres to the skull; white fibrous tissue
Subdural space	Between the dura mater and the arachnoid membrane	Cushion of lubricating serous fluid
Arachnoid membrane	Between the dura mater and pia mater	Delicate, cobweblike membrane covering the brain and spinal cord
Subarachnoid space	Beneath the arachnoid membrane	Contains a significant amount of cerebrospinal fluid in an adult (~125–150 mL)
Pia mater	Beneath the subarachnoid space	Adheres to the outer surface of the brain and spinal cord; contains blood vessels

Purulent Meningitis

A patient with **purulent meningitis** typically has a marked, acute inflammatory exudative CSF containing large numbers of polymorphonuclear cells (PMNs). The underlying CNS tissue, in particular the ventricles, is often involved. If the ventricles become involved, this process is referred to as **ventriculitis.** Bacterial organisms are usually the cause of these infections.

Pathogenesis. The outcome of a host-microbe interaction depends on the characteristics of both the host and the microorganism. As previously indicated, an important host defense mechanism within the CNS is the blood-brain barrier; this barrier involves the choroid plexus, arachnoid membrane, and the cerebral microvascular endothelium. The unique structural properties of the vascular endothelium, such as the continuous intercellular tight junctions, provide a barrier minimizing the passage of infectious agents into the CSF. The normal function of the vascular endothelium includes regulating the transport of nutrients into and out of the CSF, including low-molecular-weight plasma proteins, glucose, and electrolytes.

The host's age and other underlying factors contribute to whether an individual is predisposed to the development of infectious meningitis. Neonates have the highest infection rate for meningitis, because of the immature neonatal immune system, the increased permeability of the blood-brain barrier in newborns, and the presence of colonizing bacteria in the female vaginal tract that can pass to the infant during childbirth. The most common bacterial pathogens responsible for meningitis in newborns are group B streptococci, *Escherichia coli,* and *Listeria monocytogenes.* Before the advent of the *Haemophilus influenzae* type b (Hib) vaccine in the United States in 1985, Hib was a common cause of meningitis in children 4 months to 5 years of age. Because of the incorporation of Hib into childhood immunization programs, childhood Hib disease has dramatically declined not only in the United States, but worldwide.

Among young adults, *Neisseria meningitidis* is typically the agent that is associated with meningitis. *N. meningitidis* has been identified in epidemics among young adults in crowded conditions (e.g., military recruits and college dormitories). There are two types of meningococcal vaccines (vaccines for *N. meningitidis*) available in the United States: meningococcal conjugate vaccines (for young adults 11 to 12 years of age), with a booster recommended at the age of 16, and serogroup B meningococcal vaccines (16 to 35 years of age). *Streptococcus pneumoniae* is a common cause of meningitis in young children and the elderly; often this meningitis develops from bacteremia or from infection of the sinuses or middle ear. There are two pneumococcal vaccines (vaccines for *S. pneumoniae*) that are recommended currently in the United States. The pneumococcal conjugate

vaccine (PCV13) protects against infection from 13 different serotypes of *S. pneumoniae* and is used for vaccination of children and adults. The second vaccine, pneumococcal polysaccharide vaccine (PPSV), provides protection from 23 serotypes of *S. pneumoniae,* including those associated with serious life-threatening infections. This vaccine is recommended for adults 65 years of age and older or anyone over the age of 19 years who has long-term health problems or is immunocompromised.

Because the respiratory tract is the primary portal of entry for many etiologic agents of meningitis, factors that predispose adults to meningitis are often the same factors that increase the likelihood for the development of pneumonia or other respiratory tract colonization or infection. Alcoholism, splenectomy, diabetes mellitus, prosthetic devices, and immunosuppression contribute to increased risk. Finally, patients with prosthetic devices, particularly CNS and ventriculoperitoneal shunts, are at increased risk for developing meningitis.

For organisms to reach the CNS (primarily by the bloodborne route), host defense mechanisms must be overcome. Most cases of meningitis are a result of bacteria that share a similar pathogenesis. The successful meningeal pathogen must first sequentially colonize and cross host mucosal epithelium, then enter and thrive within the bloodstream. The most common causes of meningitis possess the ability to evade host defenses at each of these levels. For example, clinical isolates of *S. pneumoniae* and *N. meningitidis* secrete IgA proteases capable of destroying the host's secretory IgA, thereby facilitating bacterial attachment to the epithelium. In addition, all the most common etiologic agents of bacterial meningitis possess an antiphagocytic capsule that allows the organisms to evade destruction by the host immune system.

Organisms appear to enter the CNS by interacting and subsequently breaking down the blood-brain barrier at the level of microvascular endothelium. One of the least understood processes in the pathogenesis of meningitis is how organisms cross this barrier into the subarachnoid space. Nevertheless, there appear to be specific bacterial surface components, such as pili, polysaccharide capsules, and lipoteichoic acids, which facilitate adhesion of the organisms to the microvascular endothelial cells and subsequent penetration into the CSF. Organisms can enter (1) through loss of capillary integrity by disrupting tight junctions of the blood-brain barrier, (2) through transport within circulating phagocytic cells, or (3) by crossing the endothelial cell lining within endothelial cell vacuoles. After gaining access, the organism multiplies within the CSF, a site initially free of antimicrobial antibodies or phagocytic cells.

Clinical Manifestations. Meningitis can be classified as either an acute or a chronic disease in the onset and overall progression within the host. It is important to note that not all patients will present with the classic signs and symptoms associated with CNS infection discussed in this chapter. One example is the presence of seizures. Seizures may assist in the differentiation of meningitis from encephalitis. Seizures are generally a late clinical manifestation in meningitis and an early indicator in encephalitis. Computed tomography (CT) of the head and neck should be completed prior to a CSF lumbar puncture in immunocompromised patients, patients with a decreased level of consciousness, or focal neurological defects to rule out noninfectious disease.

Acute. Classical symptoms of acute meningitis include fever, stiff neck, headache, nausea and vomiting, neurologic abnormalities, and change in mental status.

In acute bacterial meningitis, the CSF usually contains large numbers of inflammatory cells (>1000/mm^3), primarily PMNs. The CSF shows a decreased glucose level relative to the serum glucose level and an increase in protein concentration. In a healthy individual, the normal CSF glucose level is 0.6 of the serum glucose level and ranges from 45 to 100 mg/dL; the CSF protein range in an adult is 15 to 50 mg/dL; newborn CSF protein ranges run as high as 170 mg/dL, with an average of 90 mg/dL.

The sequelae of acute bacterial meningitis in children are common and serious. Seizures occur in 20% to 30% of patients, and other neurologic changes are common. Acute sequelae include cerebral edema, hydrocephalus, cerebral herniation, and focal neurologic changes. Permanent deafness can occur in 10% of children who recover from bacterial meningitis. Other subtle physiologic and psychological sequelae may also follow an episode of acute bacterial meningitis.

Chronic. Chronic meningitis is common in patients who are immunocompromised, although this is not always the case. Patients experience an insidious onset of disease, with some or all the following symptoms: fever, headache, stiff neck, nausea and vomiting, lethargy, confusion, and mental deterioration. Symptoms may persist for a month or longer before treatment is sought. The CSF usually manifests an abnormal number of white blood cells (usually lymphocytic), elevated protein, and decrease in glucose content (Table 70.2). The pathogenesis of chronic meningitis is similar to that of acute disease.

Epidemiology and Etiologic Agents of Acute Meningitis. The cause of acute meningitis depends on the age of the patient. Most cases in the United States occur in children younger than 5 years of age. Before 1985, *H. influenzae* type b was the most common infectious agent in children between 1 month and 6 years of age within the United States. Ninety-five percent of all cases were caused by *H. influenzae* type b, *N. meningitidis,* and *S. pneumoniae.* In 1985, the first Hib vaccine, a polysaccharide vaccine, was licensed for use in children 18 months of age or older but was not efficacious in children younger than 18 months. However, the widespread use of conjugate vaccine, Hib polysaccharide-protein conjugate, in children as young as 2 months of age, has significantly affected the incidence of invasive *H. influenzae* type b disease; the total number of annual cases of *H. influenzae* disease has decreased significantly in the United States and Europe and the number of cases of *H. influenzae* meningitis by 94%. However, the risks for meningococcal and pneumococcal diseases resulting from agents other than *H. influenzae* have remained

TABLE 70.2 **Guidelines for Interpretation of Results After Hematologic and Chemical Analysis of Cerebrospinal Fluid From Children and Adults (Excluding Neonates)**

Clinical Setting	Leukocytes (mm³)	Predominant Cell Type	Protein	Glucose[a]
Normal	0–5	None	15–50 mg/dL	45–100 mg/dL
Viral infection	2–2000 (mean of 80)	Mononuclear[b]	Slightly elevated (50–100 mg/dL) or normal	Normal
Purulent infection	5–20,000 (mean of 800)	Polymorphonuclear	Elevated (>100 mg/dL)	Low (<45 mg/dL), but may be normal early during disease
Tuberculosis and fungi	5–2000 (mean of 100)	Mononuclear	Elevated (>50 mg/dL)	Normal or often low (>45 mg/dL)

[a] Must consider cerebrospinal fluid (CSF) glucose level in relation to blood glucose level. Normally, the CSF glucose serum ratio is 0.6, or 50%–70% of the blood glucose normal value.

[b] About 20%–75% of cases may have PMN leukocytosis early during infection.

level. Children older than 6 years are less likely to develop meningitis, but the risk for meningitis infection increases when the child reaches early adulthood. As previously mentioned, neonates have the highest incidence of acute meningitis, with a concomitant increased mortality rate (as high as 20%). Organisms causing disease in the newborn are different from those that affect other age groups; many of them are acquired by the newborn during passage through the mother's vaginal vault. Neonates are likely to be infected with, in order of incidence, group B streptococci, *Escherichia coli,* other gram-negative bacilli, and *Listeria monocytogenes;* occasionally other organisms may be involved. For example, *Elizabethkingia meningoseptica* and *Elizabethkingia anopheles* are both associated with severe cases of neonatal meningitis. These organisms are normal inhabitants of water in the environment and may be transmitted from mother to fetus or acquired as a nosocomial infection.

Important causes of meningitis in adults, in addition to the meningococcus in young adults, include pneumococci, *L. monocytogenes,* and, less commonly, *Staphylococcus aureus* and various gram-negative bacilli (*E. coli, Klebsiella* spp., *Serratia marcescens, Pseudomonas aeruginosa, Acinetobacter* spp., and *Salmonella* spp.). Meningitis caused by the latter organisms results from hematogenous seeding from various sources, including urinary tract infections. Spirochetal meningitis or neurosyphilis can be caused by dissemination of *Treponema pallidum* early in the infectious process. CSF abnormalities may occur in up to 9% of patients who are seronegative for syphilis and may overlap in clinical presentation, including asymptomatic, meningeal, meningovascular, parenchymatous, and gummatous. Although *Naegleria fowleri* is the primary cause of meningoencephalitis, additional genera may also be associated with infection, including *Acanthamoeba* and *Balamuthia. Parastrongylus cantonensis* is the most common cause of eosinophilic meningitis or encephalitis. The nematode larvae invade the CSF directly from the bloodstream and mature into adult worms migrating throughout the brain. Additional organisms capable of causing eosinophilic meningitis include *Paragonimus westermani*, *Gnathostoma* spp. (myeloencephalitis), *Baylisascaris procyonis* (neural larva migrans [NLM]), and *Taenia solium.*

Aseptic Meningitis

Aseptic meningitis is usually viral and is characterized by an increase of lymphocytes and other mononuclear cells (pleocytosis) in the CSF; bacterial and fungal cultures are negative. This contrasts with bacterial meningitis, which is characterized by purulence and the PMN cell response in the CSF. However, viral meningitis may mimic bacterial meningitis with an increase in PMNs within the first 24 hours followed by a transition to a lymphocytic pleocytosis. Aseptic meningitis is usually self-limiting, with symptoms that may include fever, headache, stiff neck, nausea, and vomiting.

In addition to the increase of lymphocytes and other mononuclear cells in the CSF, the glucose level remains normal, whereas the protein CSF level may remain normal or may be slightly elevated. Aseptic meningitis can also be a symptom for syphilis and some other spirochete diseases (e.g., leptospirosis and Lyme borreliosis). Stiff neck and CSF pleocytosis may also be associated with other disease processes, such as malignancy.

Enteroviruses are currently the leading cause of aseptic meningitis. Infants and young children are the most common population susceptible to infection. Additional viral agents associated with aseptic meningitis include herpes simplex virus (HSV); varicella-zoster-virus (VZV); cytomegalovirus (CMV); Epstein-Barr virus (EBV); and human herpesviruses 6, 7, and 8. The mumps virus may contribute to aseptic meningitis cases in nonimmunized populations.

Encephalitis/Meningoencephalitis

There are over 100 different pathogens capable of causing encephalitis. Encephalitis is an acute inflammation of the brain parenchyma and is usually caused by direct viral invasion. Concomitant meningitis occurring with encephalitis is known as **meningoencephalitis**, and the cellular infiltrate present in the CSF is typically lymphocytic rather than PMNs.

The host response to these CNS infections can differ somewhat from those associated with purulent or aseptic meningitis. Early during viral encephalitis, or when considerable tissue damage occurs as a part of encephalitis, the nature of the inflammatory cells found in the CSF may be no different from that associated with bacterial meningitis; cell counts, however, are typically much lower.

Viral Encephalitis

Viral encephalitis, which cannot always be distinguished clinically from meningitis, is common in the warmer months. The primary agents are enteroviruses (coxsackie viruses A and B and echoviruses), mumps virus, herpes simplex virus, and arboviruses (West Nile virus, togavirus, bunyavirus, equine encephalitis, St. Louis encephalitis, and other encephalitis viruses). Herpes simplex virus is the most common virus associated with viral encephalitis in developed countries. Other viruses—such as measles, cytomegalovirus, lymphocytic choriomeningitis, Epstein-Barr virus, hepatitis, varicella-zoster virus, rabies virus, myxoviruses, and paramyxoviruses—are less commonly encountered. Any preceding viral illness and exposure history are important considerations in establishing a cause by clinical means.

West Nile virus is the most common flavivirus reported in the United States with cases identified in all 48 contiguous states. Neuroinvasive infection with West Nile presents with symptoms of headache, fever, and a change in consciousness along with altered mental status. Examination of the CSF shows an increase in leukocytes with a marked increase in lymphocytes. Chemistries demonstrate an elevated protein count and normal glucose levels. Definitive diagnosis requires testing for the presence of the IgM antibody to West Nile in the serum or CSF, and because IgM does not cross the blood-brain barrier, presence of IgM antibody to West Nile in the CSF is a strong indicator for CNS infection. Polymerase chain reaction (PCR) can also be used to test for West Nile infection, but because West Nile infections have a transient and low viremia, results must be interpreted with caution. A negative result does not necessarily rule out West Nile infection.

Involvement of the nervous system in patients who are infected with the human immunodeficiency virus (HIV) is common. HIV is a neurotropic (attracted to nerve cells) virus capable of entering the CNS by macrophage transport and is the cause of various neurologic syndromes. As HIV-infected individuals become progressively more immunosuppressed, the CNS becomes a target for opportunistic pathogens, such as cytomegalovirus, BK virus, and JC (John Cunningham) virus, which can produce meningitis or encephalitis. BK virus is named after the initials of the first renal transplant patient where the virus was identified in association with clinical disease.

Parasitic Infections

Parasites can cause meningoencephalitis, brain abscess (see the following discussion), or other CNS infection via two routes. A rare but devastating meningoencephalitis is caused by the free-living amoeba *N. fowleri,* which invades the brain via direct extension from the nasal mucosa. These organisms are acquired during swimming or diving in natural, stagnating freshwater ponds and lakes. Although *N. fowleri* is the primary cause of meningoencephalitis, additional genera may also be associated with infection including *Balamuthia* spp. and *Acanthamoeba* spp. (granulomatous amebic encephalitis); *Sappinia pedata*, is now a confirmed human parasitic pathogen linked to the development of encephalitis.

Other parasites reach the brain via hematogenous spread. Toxoplasmosis, caused by an intracellular parasite that destroys brain parenchyma, is a common CNS affliction in HIV-infected patients with acquired immune deficiency syndrome (AIDS). *Entamoeba histolytica* and *Strongyloides stercoralis* have been identified in brain tissue, and the larval form of *T. solium* (the pork tapeworm), referred to as a cysticercus, can travel to the brain via the bloodstream and encyst within the brain tissue. Amoebic brain infection and cysticercosis cause changes in the CSF that are similar to meningitis.

Parastrongylus cantonensis is the most common cause of eosinophilic meningitis. The nematode larvae invade the CSF directly from the bloodstream and mature into adult worms migrating throughout the brain. Additional organisms capable of causing eosinophilic meningitis include *Gnathostoma* spp., *Baylisascaris procyonis, Paragonimus westermani*, and *T. solium.* Symptoms include headache and visual disturbances. Approximately 50% of the patients' experience vomiting and moderate fever. Approximately 10% to 20% of patients infected with *Trichinella spiralis* may exhibit CNS involvement with a mortality rate of 50% if untreated. Symptoms can mimic meningitis or encephalitis.

Brain Abscess

Brain abscesses (localized collections of pus in a cavity formed by the breakdown of tissue) may occasionally cause changes in the CSF and clinical symptoms similar to meningitis. Brain abscesses result from contiguous infection of the sinuses, middle ear, or mastoids (25% to 50%), hematogenously (15% to 30%), or through direct inoculation as a result of trauma or surgery (8% to 19%). Brain abscesses may rupture into the subarachnoid space, producing severe meningitis with a high mortality rate. If anaerobic organisms or viridans streptococci are recovered from CSF cultures, the diagnosis of brain abscess should be considered; however, CSF culture is typically negative in brain abscess. Patients who are immunosuppressed or who have diabetes with ketoacidosis may present with a rapid progressive fungal infection (phycomycosis) of the nasal sinuses or palatal region capable of traveling directly to the brain. The complex polymicrobial infections isolated from brain abscesses are far too extensive to list.

Shunt Infections

Information and studies related to infections involving CSF shunts is limited. The organisms reported to be most commonly associated with infections include coagulase-negative staphylococcus, *S. aureus, Propionibacterium acnes,* and viridians group streptococci. A few gram-negative rods have been identified, including *P. aeruginosa, Klebsiella* spp., *E. coli,* and *S. marcescens.* Positive cultures are most often associated with shunt tip cultures, shunt valves, and cerebral ventricle fluid.

Laboratory Diagnosis of Central Nervous System Infections

Meningitis

Except in unusual circumstances, a lumbar puncture (spinal tap) is one of the first steps in the diagnosis of a patient with suspected CNS infection, in particular, meningitis. Refer to Table 5.1 to review the procedure for collecting, transporting, and processing specimens obtained from the central nervous system.

Specimen Collection and Transport

CSF is collected by aseptically inserting a needle into the subarachnoid space (lumbar puncture), at the lumbar spine region between L3, L4, or L5. Three or four tubes of CSF should be collected into sterile collection tubes that contain no additives. The tubes are numbered sequentially in the order in which they were collected along with the patient's name. When processing the CSF collection tubes in the laboratory, tube 1 is used for chemistry studies, glucose and protein count, and immunology studies, because these tests are least affected by the presence of blood cells or bacteria introduced as a result of the spinal tap procedure; tube 2 is used for culture, allowing a larger proportion of the total fluid to be concentrated, which can facilitate the detection of infectious agents present in low numbers; tubes 3 and 4 are used for cell count and differential, because these tubes are least likely to contain cells introduced by the collection procedure. If a small capillary blood vessel is inadvertently broken during the spinal tap, blood cells picked up from this source will usually be absent from the last tube collected; comparison of counts between tubes 1 and 3 or 4 is occasionally needed if a traumatic tap is suspected or to differentiate a traumatic bloody tap from a true subarachnoid hemorrhage. In a traumatic tap, the red blood cells will be unevenly distributed among the three tubes, with the heaviest concentration of red blood cells in tube 1 and diminishing amounts in all subsequent tubes. In an intracranial hemorrhage, the red blood cells will be evenly distributed among all the tubes. If only one tube of CSF is collected, it should be submitted to microbiology first. The volume of CSF that can be collected is based on the volume available in the patient (adult versus neonate) and the opening pressure of the CSF when the needle first punctures the subarachnoid space. An elevated pressure requires the CSF fluid to be withdrawn more slowly, which may prevent the collection of a larger volume. The volume of CSF is critical for detecting certain microorganisms, such as mycobacteria and fungi. A minimum of 5 to 10 mL is recommended for detecting these agents by centrifugation and subsequent culture. When the laboratory receives an inadequate volume of CSF, the physician should be consulted regarding the order of priority for laboratory tests. Processing too little specimen lowers the sensitivity of laboratory tests, which may lead to false-negative results. This is potentially more harmful to patient care than performing an additional lumbar puncture to obtain the necessary amount of sample.

CSF should be hand-delivered immediately (≤15 minutes at room temperature) to the laboratory. Certain agents, such as *S. pneumoniae,* may not be detectable after an hour or longer. Specimens for microbiology studies should never be refrigerated; if not rapidly processed, CSF should be incubated (35°C) or left at room temperature. One exception to this rule involves CSF for viral studies. These specimens may be refrigerated for as long as 48 hours after collection or frozen at −70°C if a longer delay is anticipated until they are processed and inoculated into culture media. CSF for viral studies should never be frozen at temperatures above −70°C. CSF samples for viral identification should also not be added to transport media as they do not require antimicrobials to suppress other microorganisms. In addition, dilution using transport media may cause false-negative results. If not processed immediately, CSF specimen for hematology studies can be refrigerated, whereas the CSF for chemistry and serology can be frozen (−20°C).

Information gathered from specimen analysis should be promptly relayed to the clinician, who can directly affect therapeutic outcome. Such specimens should be processed immediately upon receipt in the laboratory (STAT) and results reported to the physician as soon as possible.

Initial Processing

Initial processing of CSF for bacterial, fungal, or parasitic studies includes centrifugation of all specimens with a volume greater than 1 mL for least 15 minutes at 1500×*g*. CSF specimens collected for viral nucleic acid–based tests should not be centrifuged prior to nucleic acid extraction, as most viral nucleic acid will be cell associated. Specimens in which cryptococci or mycobacteria are suspected require special handling. (Discussions of techniques for culturing CSF for mycobacteria and fungi are found in Chapters 42 and 58, respectively.) If less than 1 mL of CSF is available, the specimens should be Gram stained and plated directly to blood, chocolate agar, and primary fungal isolation media, when appropriate. For bacterial culture, the supernatant is removed to a sterile tube, leaving approximately 0.5 mL of fluid. For fungal culture, the supernatant should not be removed unless a portion is required for cryptococcal antigen testing. The remaining fluid is used to suspend the sediment for visual examination or culture. Mixing of the sediment after the supernatant has been removed is critical for bacterial culture. Forcefully aspirating the sediment up and down into a sterile pipette several times will adequately disperse the organisms that remained adherent to the bottom of the tube after centrifugation. Laboratories that use a sterile pipette to remove portions of the sediment from underneath the supernatant will miss a significant number of positive specimens. The supernatant can be used to test for the presence of antigens, for rapid diagnostic tests (vertical flow immunochromatography), to test for *N. meningitidis,* or for chemistry evaluations (e.g., protein, glucose, lactate, C-reactive protein). As a safeguard, the laboratorian should keep the supernatant even if it has no immediate use.

Cerebrospinal Fluid Laboratory Results

As previously mentioned, CSF is also removed for analysis of cells, protein, and glucose. Ideally, the glucose content of the peripheral blood is determined simultaneously for comparison with CSF levels. General guidelines for the interpretation of results are shown in Table 70.2.

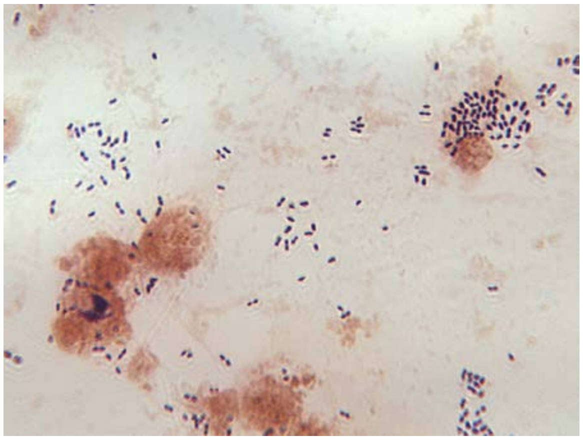
Because the results of hematologic and chemical tests directly relate to the probability of infection, communication between the physician and the microbiology laboratory is essential. The diagnosis of acute bacterial meningitis can be excluded in patients with normal fluid parameters in almost all cases, precluding further expensive and labor-intensive microbiologic processing beyond a standard smear and culture (which must be included in all cases). One exception is a patient infected with *Listeria monocytogenes.* Forty percent of patients with listeriosis demonstrate a positive CSF culture for isolation of the organism; however, the CSF may demonstrate normal cell counts and the Gram stain may not show any bacteria. *L. monocytogenes* can present as meningitis, encephalitis, abscess, or ventriculitis. Similar criteria have been used to exclude performance of smear and culture for tuberculosis and syphilis serology on CSF specimens.

Visual Detection of Etiologic Agents

After centrifugation, the resulting CSF sediment may be visually examined for the presence of cells and organisms.

Stained Smear of Sediment

Gram stain must be performed on all CSF sediments. False-positive smears have resulted from inadvertent use of contaminated slides. Therefore use of alcohol-dipped and flamed or autoclaved slides is recommended. After thoroughly mixing the sediment, a heaped drop is placed on the surface of a sterile or alcohol-cleaned slide. The sediment should never be spread out on the slide surface, because this increases the difficulty of finding small numbers of microorganisms. The drop of sediment is allowed to air dry, is heat or methanol fixed, and is stained by either Gram stain (Fig. 70.3) or acridine orange. The acridine orange fluorochrome stain may allow faster examination of the slide under high-power magnification (400×) and thus a more thorough examination. The brightly fluorescing bacteria will be easily visible. All suspicious smears can be stained using the Gram stain (directly over the acridine orange) to confirm the presence and morphology of organisms.



• **Fig. 70.3** Gram stain of cerebrospinal fluid showing white blood cells and many gram-positive diplococci. This specimen subsequently grew *Streptococcus pneumoniae.*

Using a cytospin centrifuge to prepare slides for staining has also been found to be an excellent alternative procedure. This method for preparing smears for staining concentrates cellular material and bacterial cells up to a 1000-fold. By centrifugation, a small amount of CSF (or other body fluid) is concentrated onto a circular area of a microscopic slide (Fig. 70.4), fixed, stained, and then examined.

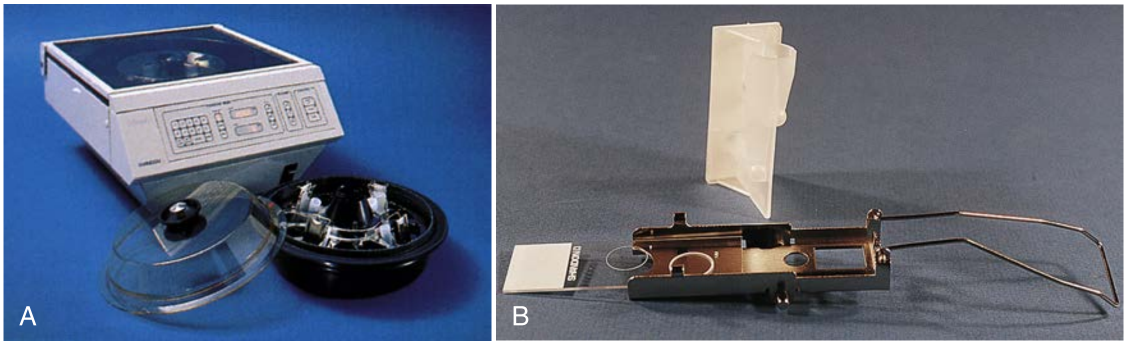
The presence or absence of bacteria, inflammatory cells, and erythrocytes should be reported after examination. Based on demographic and clinical patient data and Gram stain morphology, the cause of most bacterial meningitis cases can be presumptively determined within the first 30 minutes after receipt of the specimen.

Wet Preparation

Amoebas are best observed by examining thoroughly mixed sediment as a wet preparation under phase-contrast microscopy. If a phase-contrast microscope is not available, observing under light microscopy with the condenser closed slightly can be used as an alternative. Amoebas are identifiable by their typical slow, methodical movement in one direction via pseudopodia. The organisms may require a little time under the warm light of the microscope before they begin to move. Organisms must be distinguished from motile macrophages, which occasionally occurs in CSF. If a wet preparation is suspicious, a trichrome stain can assist in the differentiation of amoebas from somatic cells. The pathogenic amoebas can be cultured on a lawn of *K. pneumoniae* or *E. coli* (Chapter 46).

India Ink Stain

The large polysaccharide capsule of *Cryptococcus* spp. allows these organisms to be visualized by the India ink stain. However, latex agglutination testing for capsular antigen is more sensitive and extremely specific. Lateral flow assays are now available for the primary screening of CSF for suspected cases of cryptococcal meningitis. Antigen testing is



• Fig. 70.4 (A) Cytocentrifuge. (B) Device used to prepare the concentrated smears of material from body fluid specimens such as cerebrospinal fluid by cytocentrifugation. (A, Courtesy Cytospin 2, Shandon, Inc., Pittsburgh, PA.)

recommended over the use of an India ink stain. Furthermore, strains of *Cryptococcus* spp. that infect patients with AIDS may not possess detectable capsules, making culture essential. To perform the India ink preparation, a drop of CSF sediment is mixed with one-third volume of India ink. The India ink can be protected against contamination by adding 0.05 mL thimerosal (Merthiolate, Sigma Chemical Co., St. Louis, MO) to the stain. After mixing the CSF and ink to make a smooth suspension, a coverslip is applied to the drop, and the preparation is examined under high-power magnification (400×) for characteristic encapsulated yeast cells, which can be confirmed by examination under oil immersion. Inexperienced microbiologists must be careful not to confuse white blood cells with yeast. The presence of encapsulated buds, smaller than the mother cell, is diagnostic.

Direct Detection of Etiologic Agents

Antigen

Commercial reagents and kits are available for the rapid detection of antigen in the CSF; the following sections review the methodologies used; for more detailed specifics, refer to Chapter 9.

Bacteria. Rapid antigen detection from CSF has been largely accomplished by the techniques of latex agglutination (Chapter 9). All commercial agglutination systems use the principle of an antibody-coated particle capable of binding to specific antigen, resulting in macroscopically visible agglutination. The soluble capsular polysaccharide found in the common etiologic agents of meningitis, including the group B streptococcal polysaccharide, are well suited to serve as bridging antigens. The agglutination assays may contain either a polyclonal or monoclonal antibody or an antigen from an infectious agent.

In general, the commercial systems have been developed for use with CSF, urine, or serum, although results with serum have not been as diagnostically useful as those with CSF. Soluble antigens from *Streptococcus agalactiae* and *H. influenzae* may concentrate in the urine. Urine, however, seems to produce a higher incidence of nonspecific reactions than either serum or CSF. The manufacturers' directions must be followed for performance of antigen detection test systems for different specimen types. Although some of the systems require pretreatment of samples (usually heating for 5 minutes), not all manufacturers recommend pretreatment. The reagents, however, may yield false positives or cross reactions if the specimen is not pretreated. Interference by rheumatoid factor and other substances, more often present in body fluids other than CSF, has also been reported. The rapid extraction of antigen procedure (REAP; Evolve Procedure 70.1) has been shown to effectively reduce a substantial portion of nonspecific and false-positive reactions, at least for tests performed with latex particle reagents. This procedure is recommended for laboratories that use commercial body fluid antigen detection kits. Some commercial systems have an extraction procedure included in the protocol.

Based on the findings of several studies, only a limited number of clinically useful situations warrant bacterial antigen testing (BAT). Examples include CSF specimens from previously treated patients and Gram stain–negative CSF specimens with abnormal parameters (elevated protein, decreased glucose, or an abnormal white blood cell count). The assays are not substitutes for properly performed smears and cultures. Some of the assays demonstrate a decreased sensitivity and specificity. Considering these limitations, practice guidelines for the diagnosis and management of bacterial meningitis do not recommend routine use of BAT.

***Cryptococcus* spp.** Reagents for the detection of the polysaccharide capsular antigen of *Cryptococcus* spp. are available commercially. CSF specimens that yield positive results for cryptococcal antigen should be tested with a second latex agglutination test for rheumatoid factor. The commercial test systems incorporate rheumatoid factor testing in the protocol. A positive rheumatoid factor test renders the cryptococcal latex test uninterpretable, and the results should be reported as such, unless the rheumatoid factor antibodies have been inactivated. Undiluted specimens used in latex agglutination assays or enzyme immunoassays containing large amounts of capsular antigen may yield a false-negative reaction caused by a prozone phenomenon. Patients with AIDS may have an antigen titer more than 100,000, requiring many dilutions to reach an end-point. Serial dilution protocols are useful for monitoring a patient's response to treatment, as well as for initial diagnosis.

Lateral flow assays are now available (the IMMY cryptococcal LFA [Abacus ALS, Meadowbrook, Queensland, Australia]), and demonstrate superior sensitivity to latex agglutination assays. In addition, the turn-around time for results is shorter, and they can be used on urine samples and capillary blood samples.

Nucleic Acid Detection

Traditional methods, including Gram stain and culture, can take several days to identify the etiological agent associated with CSF infections resulting in prolonged antimicrobial therapies and lengthened hospital stays. With the introduction of amplification technologies, such as PCR, many reports in the literature recommend the application of nucleic acid–based technologies for the diagnosis of CNS infections caused by various microorganisms. Published data indicate that nucleic acid–based assays demonstrate increased sensitivity and specificity compared with presently available techniques, particularly of CNS infections caused by herpes simplex virus and enteroviruses. PCR testing for HSV, EBV, CMV, and enterovirus in CNS infections has a sensitivity nearing 100%.

The FilmArray meningitis/encephalitis panel (BioFire Diagnostics, Salt Lake City, UT) is a US Food and Drug Administration (FDA)-cleared, multiplex panel that detects 14 pathogens including 6 bacterial, 1 fungal, and 7 viral infectious agents. It is estimated that up to 50% of cases of encephalitis and 60% of cases of meningitis fail to identify an etiological agent. Delays in treatment may result in increased morbidity and mortality, and unnecessary treatment promotes the development of antibiotic resistance and increased health care costs. However, a retrospective study by Dack and colleagues indicates that the use of the BioFire FilmArray does not significantly reduce the length of stay or antimicrobial treatment associated with meningitis. This may be due to factors that include clinicians concerned with other health care–associated risks and continuing antimicrobial therapy in the presence of negative results. A significant advantage to using traditional culture methods in combination with nucleic acid–based testing is the identification of CSF infections that include more than one infectious pathogen. Although a low percentage, the FilmArray ME panel has been reported to identify several cases of coinfections when routine testing resulted in the identification of a single pathogen. Examples include bacterial and fungal pathogens such as *H. influenzae* and *L. monocytogenes, Cryptococcus* spp. and *S. pneumoniae*, *N. meningitidis,* and *S. pneumoniae.* Other coinfections included viral agents such as HSV-1 and HHV-6, CMV, and VZV, or combination bacterial viral infection with *H. influenzae* and HHV-6 or a combination fungal and viral infection with *Cryptococcus* spp. and HSV-1. Other advanced techniques are continually being developed, including an advanced fragment PCR based analysis capable of identifying 22 different pathogens associated with meningitis or encephalitis by F. Long et al. PCR analysis has also been successfully used to diagnose neurosyphilis. Additional multiplex laboratory developed tests not only include bacterial, fungal, and viral agents, but others also include the detection of the free-living amoebic parasites *Balamuthia mandrillaris* and *Acanthamoeba*. The successful detection of parasites in CNS using these assays has not demonstrated sufficient clinical sensitivity and false positive results. The identification of parasitic pathogens in the CNS using nucleic acid testing requires extensive development and evaluation. Although nucleic acid–based testing does not appear to decrease length of stay or the use of antimicrobials associated with bacterial, fungal, and viral pathogens, the diagnostic sensitivity and specificity, along with the identification of pathogens that are not detected by traditional methods and the identification of rare coinfections, are significant and support the use of nucleic acid–based testing in the diagnosis and treatment of CSF infections. A variety of nucleic acid–based testing methods are now currently available.

Next generation sequencing, although not widely available in routine clinical laboratories, has been used to identify pathogens in undiagnosed infectious encephalitis. Reports include the identification of astrovirus and neuroleptospirosis both in immunocompromised patients, HSV-1, HSV-2, and *Brucella* sp. in multiple cases of neurobrucellosis. The diagnosis of neurobrucellosis is significantly challenging as the signs and symptoms are extremely nonspecific and resemble other infectious diseases including tuberculosis, syphilis, Lyme disease, and *Cryptococcus* spp. infection. Traditional methods for the diagnosis of neurobrucellosis demonstrate a very low sensitivity; 28% demonstrate positive blood cultures and 15% show positive CSF cultures. These cases indicate a significant important step in the rapid and accurate diagnosis for patients of unexpected diagnoses in suspected cases of CNS infections using next generation sequencing.

Matrix-Assisted Laser Desorption Ionization Time-of-Flight Mass Spectrometry

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) requires growth of the organism before application and spectral analysis. Studies are currently underway to determine the efficiency for the direct detection of microorganisms in CSF in cases of bacterial meningitis. A study by Bishop et al., using fresh CSF samples, demonstrated a sensitivity of 76.2% for the identification of gram-negative bacilli postneurosurgical meningitis; however, for gram-positive cocci postsurgical and community-acquired meningitis, only a single sample was identified correctly. The interpretation of direct specimen Gram stains, followed by culture or nucleic acid–based testing, remain the gold standard for directing empirical antibiotic treatment of patients in suspected cases of meningitis, encephalitis, and other CNS infections.

Culture

Most cases of bacterial meningitis are caused by a single organism and require a limited number of culture media.

Bacteria and Fungi

Routine bacteriologic media should include a chocolate agar plate, 5% sheep blood agar plate, and an enrichment broth, usually thioglycolate without indicator. The chocolate agar plate is needed to recover fastidious organisms, most notably *H. influenzae,* which are unable to grow on blood agar plates; the use of the blood agar plate aids in the recognition of *S. pneumoniae.* After vortexing the sediment and preparing smears, several drops of the sediment should be inoculated to each medium. Plates should be incubated at 37°C in 5% to 10% carbon dioxide (CO_2) for at least 72 hours. If a CO_2 incubator is not available, a candle jar or an automated environmental vacuum system can be used to create a CO_2-enriched atmosphere. The broth should be incubated in air at 37°C for at least 5 to 10 days. The broth cap must be loose to allow free exchange of air. If organisms morphologically resembling anaerobic bacteria are seen on the Gram stain or if a brain abscess is suspected, an anaerobic blood agar plate may also be inoculated. These media will support the growth of almost all bacterial pathogens and several fungi.

The symptoms of chronic meningitis that prompt a physician to request fungal cultures are the same as those for tuberculous meningitis. Cultures for mycobacteria are addressed in Chapter 42. For CSF fungal cultures, two drops of the well-mixed sediment should be inoculated onto Sabouraud dextrose agar or other non–blood-containing medium and brain-heart infusion with 5% sheep blood. Fungal media should be incubated in room air at 30°C for 4 weeks. If possible, two sets of media should be inoculated, with one set incubated at 30°C and the other at 35°C.

Parasites and Viruses

Conditions for the culture of free-living amoebae and viral agents are discussed in Chapters 46 and 64, respectively. The physician must notify the laboratory to culture these agents.

Brain Abscess/Biopsies

Specimen Collection, Transport, and Processing. Whenever possible, biopsy specimens or aspirates from brain abscesses should be submitted to the laboratory under anaerobic conditions. Several devices are commercially available to transport biopsy specimens under anaerobic conditions. Swabs are not considered an optimum specimen, but if used to collect abscess material they should be sent in a transport device that maintains an anaerobic environment.

Biopsy specimens should be minced in sterile saline before plating and smear preparation. This processing should be kept to a minimum to reduce oxygenation.

Abscess and biopsy specimens submitted for culture should be inoculated onto 5% sheep blood and chocolate agar plates. Plates should be incubated in 5% to 10% CO_2 for 72 hours at 35°C. In addition, an anaerobic agar plate and broth with an anaerobic indicator, vitamin K, and hemin should be inoculated and incubated in an anaerobic environment at 35°C. Anaerobic culture plates are incubated for a minimum of 72 hours but are examined after 48 hours of incubation. Anaerobic broths should be incubated for a minimum of 5 days. If a fungal cause is suspected, fungal media, such as brain-heart infusion with blood and antibiotics or inhibitory mold agar, should be inoculated.

PROCEDURE 70.1

Rapid Extraction of Antigen Procedure

Principle

Removal of nonspecific cross-reactive material can improve the specificity of direct antigen detection particle agglutination tests. Ethylenediaminetetraacetic acid (EDTA) forms complexes with cross-reactive materials, and they are removed from the reaction mixture by centrifugation.

Method

1. Pipette 0.05 mL fluid to be tested (cerebrospinal fluid [CSF], serum, or urine) into a 1.5-mL plastic, conical microcentrifuge tube.
2. Add 0.15 mL of 0.1 M EDTA (Sigma Chemical Co.) to the microcentrifuge tube, close the cap tightly, and vortex the tube.
3. Heat in a dry bath (available from instrument supply companies) for 3 minutes at 100°C.
4. Centrifuge the tubes for 5 minutes at 13,000×*g* in a tabletop microcentrifuge. Be certain that the instrument achieves the required centrifugal force.
5. Remove the supernatant with a capillary pipette and use 1 drop of this solution as the test sample in the antigen detection test, following the manufacturer's instructions for performance of the test.

Expected Results

Nonspecific agglutination should not occur.

CASE STUDY 70.1

A 2-year-old girl presented at midnight to the hospital emergency department with a temperature of 104°F. She was diagnosed with bilateral otitis. She was treated with amoxicillin/clavulanic acid and retained for observation in the hospital. During the night, the child became lethargic. She developed purpura and nuchal rigidity. A CSF sample was collected, and ceftriaxone therapy was begun. No organisms were noted on Gram stain. The next day, the laboratory reported growth of a gram-negative diplococcus.

Questions

1. What is the suspected organism in this infection, and how can the laboratory rapidly identify it?
2. Is it recommended that laboratories do susceptibility testing for *N. meningitidis*?
3. How can the laboratory improve the speed with which it detects this organism in CSF?
4. What measures are taken to prevent the spread of infection among health care workers who are exposed to patients with *N. meningitidis*?

Chapter Review

1. Which of the following are specialized structures of the meninges that function to absorb the spinal fluid and allow it to pass into the blood?
   a. Leptomeninges
   b. Pia mater
   c. Arachnoid villi
   d. Dura mater

2. What bacteria are responsible for outbreaks of meningitis among neonates in hospital nurseries?
   a. *Elizabethkingia meningoseptica*
   b. *Haemophilus influenzae* type b
   c. Group B *streptococci*
   d. *Neisseria meningitides*

3. All the following are pathogenic sources capable of causing brain abscesses *except:*
   a. Anaerobes
   b. *Borrelia burgdorferi*
   c. Viridans streptococci
   d. Fungal organisms

4. When processing CSF specimens for laboratory diagnosis, the specimen appears red in some of the tubes, a sign of red blood cells and bleeding; to determine whether the blood is caused by a bloody tap or a subarachnoid hemorrhage, cell counts are done on which of the following tubes?
   a. Tubes 1 and 2
   b. Tubes 3 and 4
   c. Tubes 2 and 3
   d. Tubes 1 and 4

5. Refer to the previous question. Which tube is used for chemistry and immunologic studies?
   a. Tube 1
   b. Tube 2
   c. Tube 3
   d. Tube 4

6. Culture to determine the etiologic agent causing meningitis is set up from which CSF tube?
- **a.** Tube 1
- **b.** Tube 2
- **c.** Tube 3
- **d.** Tube 4

7. Which of the following organisms is a parasite that grows intracellularly, destroys brain parenchyma, and is a common CNS affliction in HIV-infected patients with AIDS?
- **a.** *Naegleria fowler*
- **b.** *Entamoeba histolytica*
- **c.** *Taenia solium*
- **d.** Toxoplasmosis

8. Which of the following causes of pediatric meningitis was significantly reduced as the result of an effective vaccination program?
- **a.** Group B *Streptococcus*
- **b.** *Escherichia coli*
- **c.** *Haemophilus influenzae* type b
- **d.** *Listeria monocytogenes*

9. When a physician suspects *Cryptococcus* spp. as the etiologic agent of a CNS infection, what is the best manual way to test for it?
- **a.** India ink stain
- **b.** Cryptococcal antigen test
- **c.** Culture
- **d.** Molecular testing by PCR

10. The cerebrospinal fluid that surrounds the brain and spinal fluid functions to:
- **a.** Carry essential metabolites into the neural tissue
- **b.** Protect the central nervous system against microbial invasion by phagocytosis
- **c.** Provide a means by which the brain monitors changes in the internal environment
- **d.** Both A and C

11. True or False

_____ In cushioning and providing buoyancy for the bulk of the brain, the effective weight of the brain is reduced by a factor of 30 by the CSF.

_____ The three layers of protective membranes, which surround the brain and spinal column, are called the *meninges.*

_____ The elderly population of patients has the highest prevalence of meningitis.

_____ Encephalitis is an inflammation of the brain parenchyma and is normally caused by bacteria.

_____ The first Hib vaccine was not efficacious in children younger than 18 months of age.

_____ The normal CSF glucose serum ratio is 0.6, or 50% to 70% of the blood glucose normal value.

_____ A component of syphilis infections is aseptic meningitis.

_____ CSF cultures from patients with brain abscesses are typically positive for anaerobes or viridians streptococci.

_____ CSF is found in the subdural spaces of the brain.

_____ The entire volume of CSF is exchanged every 5 to 6 hours.

_____ When collecting CSF for culture studies, it is imperative to collect the correct volume of CSF.

_____ When transporting CSF to the laboratory for bacterial studies, the CSF must be refrigerated and kept at a temperature of 2°C to 8°C.

_____ If a physician orders viral studies on a CSF and the transport to the laboratory will be longer than 2 to 3 hours after collection, the CSF specimen must be frozen at −20°C.

_____ The most sensitive method for detecting encephalitis-causing viruses in the CSF is PCR.

12. Matching: *Match each term with the correct description.*

_____ leptomeninges
_____ dura mater
_____ arachnoid membrane
_____ pia mater
_____ ventriculitis
_____ aseptic meningitis
_____ encephalitis
_____ meningo-encephalitis
_____ phycomycosis
_____ spinal tap
_____ cysticercus
_____ choroid plexus
_____ blood-brain barrier
_____ meninges
_____ meningitis

a. concomitant meningitis with encephalitis
b. membrane covering the brain and spinal cord
c. secretory cells that produce CSF
d. rapidly progressive fungal infection
e. self-limiting viral-caused meningitis
f. larval form of *Taenia solium*
g. defense mechanism for the CNS
h. pia mater and the arachnoid membrane
i. outermost membrane of the meninges
j. between the dura mater and pia mater
k. adheres to the outer surface of the brain and spinal cord
l. purulent meningitis involving the ventricles
m. infection within the subarachnoid space of the meninges
n. inflammation of the brain parenchyma
o. lumbar puncture

13. Short Answer

(1) Name the least common route of CNS infection caused by an organism.

(2) Name a unique property of the HIV virus that predisposes infected individuals to viral encephalitis.

(3) What is a cytospin centrifuge, and how does it assist in processing CSF specimens?

(4) What is diagnostic in the smear when using the India ink stain to detect the presence of *Cryptococcus* spp.?

(5) What is the purpose of the pretreatment REAP procedure? What does REAP stand for?

(6) What population of patients has the highest prevalence of meningitis? Describe the associated predisposing factors.

(7) What is one of the most critical steps in processing CSF for culture?

(8) Explain the reasoning behind using tubes 3 and 4 in CSF collection for cell count and differential.

71

Infections of the Eyes, Ears, and Sinuses

OBJECTIVES

1. Describe the anatomy of the eye, including naming the external and internal structures.
2. Name the three tissues, outer to inner, of the eyeball.
3. Differentiate normal flora of the eye and potential pathogens.
4. Describe the defense mechanisms of the eye for protection from infective agents.
5. Define the following diseases of the eye: blepharitis, hordeolum, conjunctivitis, keratitis, uveitis, and endophthalmitis.
6. List the common types of eye infections, the associated etiologic agents, and the at-risk patient population for each.
7. Define keratitis, and identify the organisms associated with the infection, the virulence factors, and the antimicrobial-resistant properties for each.
8. Define endophthalmitis, explain how it is contracted, and identify the etiologic agents.
9. Explain mycotic endophthalmitis and list the risk factors that may predispose an individual to this type of infection.
10. Define a periocular infection, and list some of the associated infectious agents and the different types of clinical presentations of the infection.
11. Identify the anatomic parts of the ear, and list the structures associated with each region within the ear.
12. Define the external ear infections acute externa otitis and chronic externa otitis; list the potential pathogens.
13. Define otitis media; differentiate acute and chronic otitis media and name the most commonly encountered pathogens and the age group most often affected by this disease.
14. Explain the laboratory method used to culture the eye and the ear, including appropriate media; describe collection and transportation requirements.
15. Differentiate acute and chronic sinusitis.
16. Explain why the organisms that cause otitis media are often the same ones responsible for sinusitis.
17. List the collection methods and culture media used for cases of sinusitis.
18. Correlate signs and symptoms of infection with the results of laboratory diagnostic procedures for the identification of the etiologic agent associated with infections of the eye, ear, and sinuses.

Eyes

Anatomy

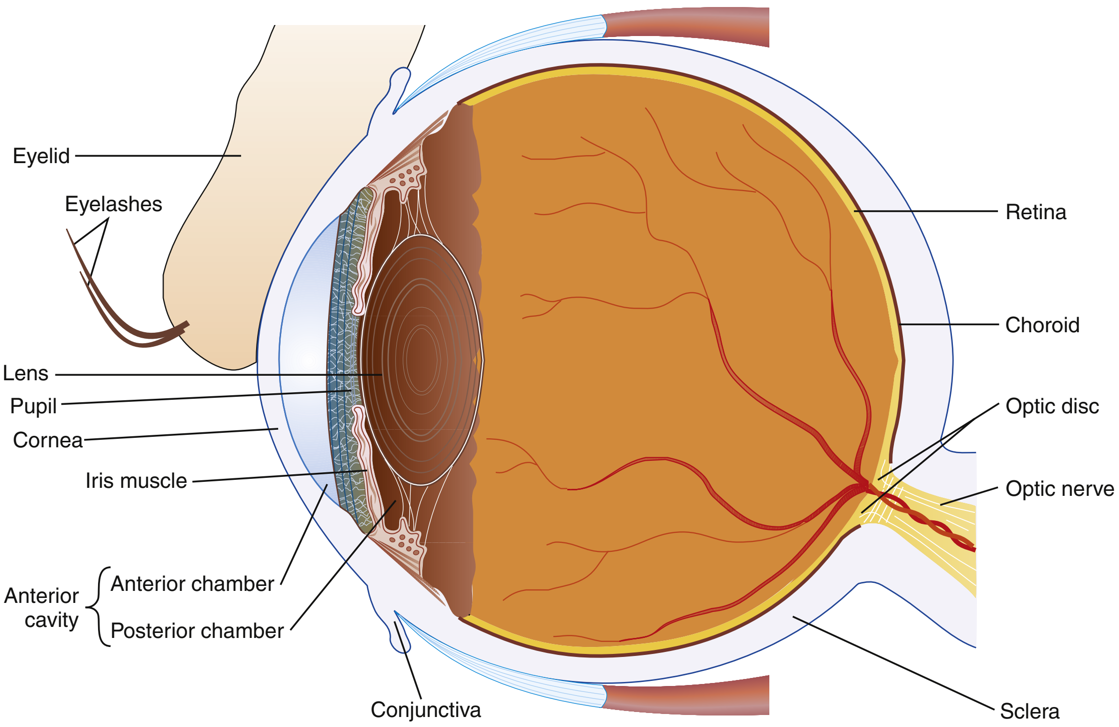
Eye (ocular) infections can be divided based on the area of the eye infected. The external structures of the eye—eyelids, conjunctiva, sclera, and cornea—are depicted in Fig. 71.1. The eyeball comprises three layers. From the outside in, these tissues are the sclera, choroid, and retina. The **sclera** is a tough, white, fibrous tissue (i.e., "white" of the eye). The anterior (toward the front) portion of the sclera is the **cornea,** which is transparent and has no blood vessels. A mucous membrane, called the **conjunctiva,** lines each eyelid and extends onto the surface of the eye itself. The **choroid** is the vascular layer of the eye that contains the connective tissue. The **retina,** the innermost layer of the eye, contains light-sensitive cells that transmit signals and images to the optical nerve.

Only a small portion of the eye is exposed to the environment; about five-sixths of the eyeball is enclosed within bony orbits shaped like four-sided pyramids. The large interior space of the eyeball is divided into two sections: the anterior and posterior cavities (Fig. 71.1). The anterior cavity is filled with a clear and watery substance called **aqueous humor;** the posterior cavity is filled with a soft, gelatin-like substance called **vitreous humor.**

Infections can occur in the eye's **lacrimal** (pertaining to tears) system. The major components of the lacrimal apparatus include the lacrimal gland, lacrimal canaliculi (short channel), and lacrimal sac.

Resident Microbiota

Rather sparse indigenous microbiota is present in the conjunctival sac. *Staphylococcus epidermidis* and *Lactobacillus* spp. are the most common organisms; *Cutibacterium acnes* may also be present. *Staphylococcus aureus* is found in less than 30% of individuals, and *Haemophilus influenzae* colonizes 0.4% to 25%. *Moraxella catarrhalis*, various Enterobacterales, and various streptococci (*Streptococcus pyogenes, Streptococcus pneumoniae,* other alpha-hemolytic and



• **Fig. 71.1** Key anatomic structures of the eye. (Modified from Thibodeau GA, Patton KT. *Anatomy and Physiology.* 2nd ed. St Louis: Mosby; 1993.)

gamma-hemolytic forms) are found in a very small percentage of individuals.

Diseases

The eye and its associated structures are uniquely predisposed to infection by various microorganisms. The major infections of the eye are listed in Table 71.1, along with a brief description of the disease.

Pathogenesis

The eye has several defense mechanisms. The eyelashes prevent the entry of foreign material into the eye. The lids blink 15 to 20 times per minute, during which time secretions of the lacrimal glands and goblet cells wash away bacteria and foreign matter. Lysozyme and immunoglobulin A (IgA) are secreted locally and serve as part of the eye's natural defense mechanisms. Also, the eyes themselves are enclosed within the bony orbits. The delicate intraocular structures are enveloped in a tough collagenous coat (sclera and cornea). If these barriers are broken by a penetrating injury or ulceration, infection may occur. Infection can also reach the eye via the bloodstream from another site of infection. Finally, because three of the four walls of the orbit are contiguous with the paranasal (facial) sinuses, sinus infections may extend directly to the periocular orbital structures.

Epidemiology and Etiology of Disease

Blepharitis and Hordeolum

Blepharitis may appear as a bump on the eyelid that is red and swollen, resembling a pimple. Most bumps on the eyelid are caused by an inflamed oil gland on the edge of the eyelid and are a form of **hordeolum**—more commonly referred to as a **stye.** A stye is more of an acute infection, whereas blepharitis tends to present as a chronic condition that can cause conjunctivitis, functional tear deficiency, or corneal inflammation and infection. Bacteria, viruses, and occasionally lice or *Demodex* mites can cause blepharitis, an infection of the eyelid surrounding the eye. Although occasionally isolated from surfaces surrounding the healthy eye, *S. aureus* and *S. epidermidis* are the most common infectious agents associated with the development of a stye and blepharitis in developed countries. Symptoms include burning, itching, the sensation of the presence of a foreign body, and crusting of the eyelids.

Viruses can also cause a vesicular (blisterlike) eruption of the eyelids. Herpes simplex virus (HSV) produces vesicles on the eyelids that typically crust and heal with scarring within 2 weeks. Unfortunately, once this vesicular stage has resolved, the lesions can be confused with bacterial blepharitis.

Finally, the pubic louse *Phthirus pubis* has a predilection for eyelash hair. The presence of this organism produces irritation, itch, and swelling of the lid margins (edges).

Conjunctivitis

Bacterial **conjunctivitis,** commonly referred to as "pink eye," is the most common type of ocular infection and may be caused by allergies, bacterial, parasitic, fungal, or viral infection. The principal causes of acute conjunctivitis in a normal host are listed in Table 71.1. Age-related factors are key in the identification of the etiologic agent. Neonatal conjunctivitis (ophthalmia neonatorum) occurs within

TABLE 71.1 Infections of the Eye

Infection	Description	Bacteria	Viruses	Fungi	Parasites
Blepharitis	Inflammation of the margins (edges) of the eyelids (eyelids, eyelashes, or associated pilosebaceous glands or meibomian glands); symptoms include irritation, redness, burning sensation, and occasional itching. Condition is typically bilateral.	*Staphylococcus aureus, Pseudomonas aeruginosa, Capnocytophaga ochracea*	Herpes simplex virus (HSV)	*Malassezia furfur, Blastomyces* sp.	*Phthirus pubis, Leishmania donovani, Demodex* mites
Conjunctivitis	Inflammation of the conjunctiva; symptoms vary according to the etiologic agent, but most patients have swelling of the conjunctiva, inflammatory exudates, and burning and itching.	*Streptococcus pneumoniae, Haemophilus influenzae, S. aureus, Haemophilus* spp., *Chlamydia trachomatis, Neisseria gonorrhoeae, Streptococcus pyogenes, Moraxella* spp., *Corynebacterium* spp., *P. aeruginosa*	Adenoviruses, HSV, varicella zoster, Epstein-Barr virus (EBV), influenza virus, paramyxovirus, rubella, human immunodeficiency virus (HIV) enterovirus, coxsackie A, variola (smallpox), SARS-CoV-2	*Candida* spp., *Blastomyces* spp., *Sporothrix schenckii, Rhinosporidium seeberi*	*Leishmania* spp., *Microsporidia* spp., *Loa loa, Demodex* (mites)
Keratitis	Inflammation of the cornea; although there are no specific clinical signs to confirm infection, most patients complain of pain and usually some decrease in vision, with or without discharge from the eye.	*S. aureus, S. epidermidis, S. pneumoniae, S. pyogenes,* viridans streptococci, *Enterococcus faecalis, Peptostreptococcus, P. aeruginosa,* Enterobacterales, *Moraxella lacunata, Bacillus* spp., *Mycobacterium* spp., spirochetes, *C. trachomatis*	HSV, adenoviruses, varicella zoster, vaccinia, Epstein-Barr, rubeola, enteroviruses, and coxsackie virus	*Fusarium, Aspergillus* spp., *Candida* spp., *Acremonium, Alternaria, Penicillium, Bipolaris, Nosema, Vittaforma, Encephalitozoon* spp.	*Acanthamoeba* spp., *Onchocerca volvulus, Leishmania brasiliensis, Trypanosoma* spp.
Keratoconjunctivitis	Infection involving both the conjunctiva and cornea; ophthalmia neonatorum is an acute conjunctivitis or keratoconjunctivitis of the newborn caused by either *N. gonorrhoeae or C. trachomatis.*	Refer to agents for keratitis/conjunctivitis	Refer to agents for keratitis/conjunctivitis	Refer to agents for keratitis	*Toxoplasma gondii, Toxocara*
Chorioretinitis and uveitis	Inflammation of the retina and underlying choroid or the uvea; infection can result in loss of vision.	*Mycobacterium tuberculosis, Treponema pallidum, Borrelia burgdorferi*	Cytomegalovirus, HSV	*Candida* spp.	*T. gondii, Toxocara, Treponema pallidum, Brucella* spp.

Continued

TABLE 71.1 **Infections of the Eye—cont'd**

Infection	Description	Bacteria	Viruses	Fungi	Parasites
Endophthalmitis	Infection of the aqueous or vitreous humor. This infection is usually caused by bacteria or fungi, is rare, develops suddenly, and progresses rapidly, often leading to blindness. Pain, especially while moving the eye, and decreased vision are prominent features.	*S. aureus, S. epidermidis, S. pneumoniae,* other streptococcal species, *P. aeruginosa, Klebsiella pneumoniae,* other gram-negative organisms, *Nocardia* spp.	HSV, varicella zoster	*Candida* spp., *Aspergillus* spp., *Fusarium* spp.	*Toxocara, Onchocerca volvulus*
Lacrimal infections, canaliculitis	A rare, chronic inflammation of the lacrimal canals in which the eyelid swells and there is a thick, mucopurulent discharge.	*Actinomyces, Propionibacterium propionicum*			
Dacryocystis	Inflammation of the lacrimal sac that is accompanied by pain, swelling, and tenderness of the soft tissue in the medial canthal region.	*S. pneumoniae, S. aureus, S. pyogenes, H. influenzae*		*C. albicans, Aspergillus* spp.	
Dacryoadenitis	Acute infection of the lacrimal gland; these infections are rare and can be accompanied by pain, redness, and swelling of the upper eyelid and conjunctival discharge.	*S. pneumoniae, S. aureus, S. pyogenes*			

Note: This table is not intended to be all-inclusive for the infectious agents capable of causing eye infections.

4 weeks following birth, caused by bacterial, viral, chlamydial, or toxic reactions to chemicals. In neonates, neisserial and chlamydial infections are common and are acquired during passage through an infected vaginal canal. With the common practice of instilling antibiotic drops into the eyes of newborns in the United States, the incidence of gonococcal and chlamydial conjunctivitis has dropped dramatically. However, *Chlamydia trachomatis* remains responsible for one of the most important types of conjunctivitis, referred to as **trachoma.** Trachoma is one of the leading causes of blindness in the world, primarily in underdeveloped countries.

In children, the most common causes of bacterial conjunctivitis include *H. influenzae*, *S. pneumoniae*, and perhaps *S. aureus*, *S. pneumoniae*, and *Haemophilus aegyptius* have been isolated from conjunctivitis epidemics. *Corynebacterium* spp. colonize the lids and conjunctiva and are the overall leading cause of conjunctivitis. Inflammation of the conjunctiva is characterized by redness, itching, and discharge, and the condition is highly contagious; it can be transferred from one eye to the other by rubbing the infected eye and can be easily transferred to other individuals.

Numerous other bacteria may also cause conjunctivitis. For example, diphtheritic conjunctivitis may occur in conjunction with diphtheria elsewhere in the body. *Moraxella lacunata* produces a localized conjunctivitis with little discharge from the eye. Distinctive clinical pictures may also occur with conjunctivitis caused by *Mycobacterium tuberculosis*, *Francisella tularensis*, *Treponema pallidum*, and *Yersinia enterocolitica*.

Fungi may be responsible for this type of infection as well, often in association with a foreign body that has been introduced into the eye or an underlying host immunologic problem. Fungi including *Candida* spp., *Blastomyces* spp., and *Sporothrix schenckii* have been associated with conjunctivitis. However, these infections are uncommon.

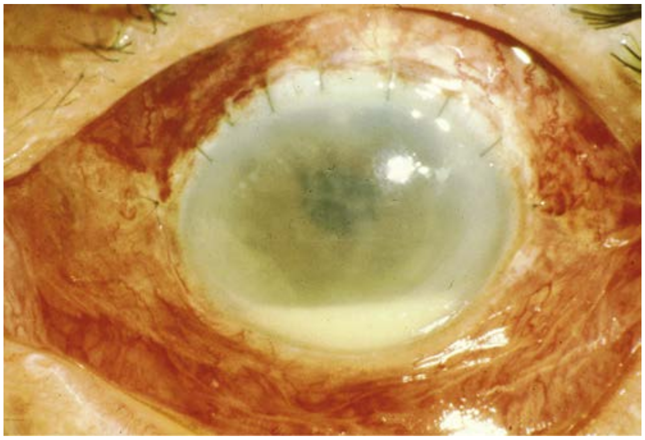
Parasitic conjunctivitis has been associated with *Leishmania* spp., cryptosporidium, fly larvae, and nematodes such as *Loa loa*. Parasites that are known to infect the lid margin or lashes, such as lice and mites, may cause conjunctivitis as a subsequent reaction to blepharitis caused by the organism.

In adults, the cause of conjunctivitis is usually viral, with adenovirus being the most common viral cause; 20% of such infections in children resulted from adenoviruses in one large US study, and 14% of infections in adult patients were caused by adenoviruses in another study. Adenovirus types 3, 4, and 7A are common. Most viral conjunctivitis is self-limited but is highly contagious, with the potential to cause major outbreaks. Worldwide, enterovirus 70 and coxsackievirus A24 are responsible for outbreaks and epidemics of acute hemorrhagic conjunctivitis. A coxsackievirus A24 variant has been reported with several outbreaks of hemorrhagic conjunctivitis in several countries. Patients can develop systemic symptoms including fever, fatigue, and limb pain; however, severe complications and death are rare. A lateral flow immunochromatographic cartridge test, the AdenoPlus (Rapid Pathogen Screening, Inc., Sarasota, FL), is available for the detection of ocular adenovirus infections. The test includes a built-in sampling pad that can be used to collect fluid by touching the eye. The assay demonstrates an 85% sensitivity and a 98% specificity, when compared with polymerase chain reaction (PCR). Negative results using the AdenoPlus should be confirmed by real-time PCR to avoid false negatives that would result in continued infection and damage to the eye.

Keratitis

Keratitis (corneal infection) may be caused by a variety of infectious agents, usually after some type of trauma to the ocular surface. Keratitis should be regarded as an emergency, because corneal perforation and loss of the eye can occur within 24 hours when organisms such as *Pseudomonas aeruginosa*, *S. aureus*, or HSV are involved. Bacteria account for 65% to 90% of corneal infections.

In the United States, *S. aureus, S. pneumoniae*, and *P. aeruginosa* account for more than 80% of all bacterial corneal ulcers. Many culture-positive cases are now being recognized as polymicrobial. A toxic factor known as **exopeptidase** has been implicated in the pathogenesis of corneal ulcer produced by *S. pneumoniae*. With *P. aeruginosa* and *Neisseria gonorrhoeae*, proteolytic enzymes are responsible for the corneal destruction. Gonococcus may cause keratitis during inadequately treated conjunctivitis. *Acinetobacter*, which may look identical microscopically to gonococcus and is resistant to penicillin and many other antimicrobial agents, can cause corneal perforation. Many other bacteria, several viruses other than HSV, and many fungi may cause keratitis. Risk factors associated with the development of fungal keratitis caused by *Candida* spp. include epithelial ulceration, topical corticosteroid use, corneal transplants, and the use of soft contact lenses. Fungal keratitis may also result as a complication of trauma.



• **Fig. 71.2** Endophthalmitis. (Courtesy Donald J. D'Amico.)

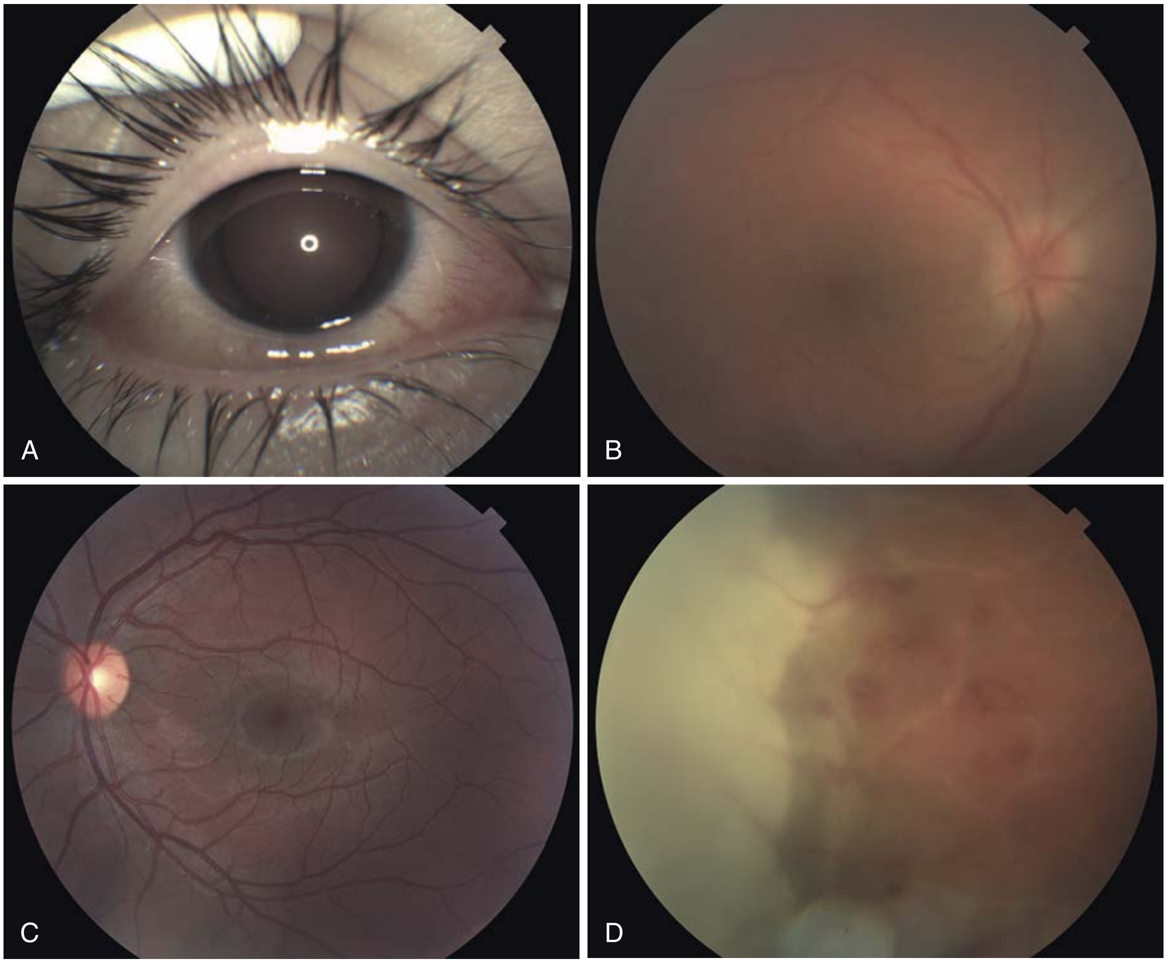
Although still unusual, a previously rare etiologic agent of corneal infections has become more common in users of soft and extended-wear contact lenses. *Acanthamoeba* spp., free-living amoebae, can survive in improperly sterilized cleaning fluids and be introduced into the eye with the contact lens. The fungus *Fusarium* is an infectious disease associated with contact lens use or contact lens solutions. This genus of fungus is ubiquitous and can be found in soil and tap water and on many plants; fungal keratitis is rare but is usually associated with trauma to the eye from an object contaminated with plant matter. This infection can be serious and can lead to the loss of vision. Other bacterial and fungal causes of infection have also been traced to inadequate cleaning of lenses.

Additional parasites are also associated with keratitis in different geographical regions, including the microfilariae *Onchocerca volvulus*, *Leishmania* spp., microsporidia, and trypanosomes. It is important to consider potential coinfections with other organisms, as that will decrease the effectiveness of the treatment and may result in the loss of vision.

Endophthalmitis

Surgical trauma, nonsurgical trauma (uncommonly), and hematogenous spread from distant sites of infection are the typical routes of transmission for **endophthalmitis** (Fig. 71.2). The infection may be limited to specific tissues within the eye or may involve all the intraocular contents. Bacteria are the most common infectious agents responsible for endophthalmitis.

After surgery or trauma, evidence of the disease is usually identified within 24 to 48 hours. Postoperative infection involves primarily normal microbiota from the ocular surface. Although *S. epidermidis* and *S. aureus* are responsible for most cases of endophthalmitis after cataract removal, any bacterium, including those considered to be saprophytic,



• **Fig. 71.3** Acute retinal necrosis caused by herpes simplex. (A) External view. (B) Limited funduscopic view. (C) Funduscopic view of the normal unaffected eye. (D) View of peripheral retina demonstrating peripheral necrotizing retinitis and vasculitis (whitening and hemorrhage).

may cause endophthalmitis. In hematogenous endophthalmitis, a septic focus elsewhere is usually evident before the onset of the intraocular infection. *Bacillus cereus* has caused endophthalmitis in people addicted to narcotics and after transfusion with contaminated blood. Endophthalmitis associated with meningitis may involve various organisms, including *H. influenzae*, streptococci, and *Neisseria meningitidis. Nocardia* endophthalmitis may follow pulmonary infection with this organism.

Mycotic infection of the eye has increased significantly since the 1980s because of the increased use of antibiotics, corticosteroids, antineoplastic chemotherapy, addictive drugs, and hyperalimentation (overeating). Fungi generally considered to be saprophytic are important causes of postoperative endophthalmitis (Table 71.1). Endogenous mycotic endophthalmitis is most often caused by *Candida albicans*. High-risk patients include those with diabetes or some other chronic underlying disease. Exogenous *Candida* spp. endophthalmitis is uncommon but may develop following surgical procedures, trauma, or keratitis. *Aspergillus* or *Fusarium* species may also be associated with trauma-related infections. Other causes of hematogenous ocular infection include *Aspergillus*, *Cryptococcus*, *Coccidioides*, *Sporothrix*, and *Blastomyces*.

Endophthalmitis may be a result of viral or parasitic infections. Viral causes of endophthalmitis include HSV (Fig. 71.3), varicella (herpes) zoster virus (VZV), cytomegalovirus, and measles viruses. The most common parasitic agent associated with endophthalmitis is *Toxocara*. *Toxoplasma gondii* is a well-known cause of **chorioretinitis.** Thirteen percent of patients with cysticercosis *(Taenia solium)* have ocular involvement. Onchocerca usually produces keratitis, but intraocular infection also occurs.

Periocular

Canaliculitis, one of three infections of the lacrimal apparatus (Table 71.1), is an inflammation of the lacrimal canal and is usually caused by *Actinomyces* or *Propionibacterium propionicum*. Infection of the lacrimal sac (**dacryocystitis**) may involve numerous bacterial and fungal agents; the major causes are listed in Table 71.1. **Dacryoadenitis** is an uncommon infection of the lacrimal gland characterized by pain of the upper eyelid with erythema and often involves pyogenic bacteria such as *S. aureus* and streptococci.

Chronic infections of the lacrimal gland occur in tuberculosis, syphilis, leprosy, and schistosomiasis. Acute inflammation of the gland may occur during mumps and infectious mononucleosis.

Orbital cellulitis is an acute infection of the orbital contents and is most often caused by bacteria. This is a potentially serious infection because it may spread posteriorly to produce central nervous system complications. Most cases involve spread from contiguous sources such as the paranasal sinuses. In children, bloodborne bacteria, notably *H. influenzae*, may lead to orbital cellulitis. *S. aureus* is the most common etiologic agent; *S. pyogenes* and *S. pneumoniae* are also common. Anaerobes may cause cellulitis secondary to chronic sinusitis, primarily in adults. Mucormycosis of the orbit is a serious, invasive fungal infection seen particularly in patients with diabetes who have poor control of their disease, patients with acidosis from other causes, and patients with malignant disease receiving cytotoxic and immunosuppressive therapy. *Aspergillus* may produce a similar infection in the same settings but also can cause mild, chronic infections of the orbit.

Surgical techniques involving the ocular implantation of prosthetic or donor lenses have resulted in increasing numbers of iatrogenic (resulting from the activities of a physician) infections. Isolation of *C. acnes* may have clinical significance in such situations, in contrast to many other sites in which it is usually considered to be a contaminant. Nontuberculous mycobacterial periocular infections have become increasingly important in patients with systemic disease. These infections are more prevalent in immunocompromised patients.

Uveitis

The **uvea** is the pigmented, middle layer of the eye that is between the cornea-sclera and the retina. Inflammation of the uvea is termed **uveitis. Retinitis,** inflammation of the retina, is also considered in this section, even though it is technically a separate structure from the uvea. There are approximately 70 to 115 cases per 100,000 individuals who are annually affected by uveitis in the United States. More than 50% of cases of uveitis are idiopathic; however, the condition may be caused by an autoimmune reaction, infection, or trauma.

Infectious uveitis typically is a result of hematogenous spread of the agent of infection. The eye has a blood-eye barrier similar to the blood-brain barrier that must be breached for an infection to occur. Inflammation causes this barrier to break down, resulting in infection. The most common causes for uveitis include herpes viruses (HSV, VZV, and cytomegalovirus) and *Toxoplasma* spp.

Other Infections

Opportunistic infections in human immunodeficiency virus (HIV)–infected individuals can involve the eye. Systemic infections that involve the eye include cytomegalovirus, *Pneumocystis jiroveci*, *Cryptococcus neoformans*, *Mycobacterium avium* complex, and *Candida* spp. Most often the retina, choroid, and optic nerve are infected with these agents, resulting in significant visual morbidity (unhealthy condition) if left untreated. However, because of the widespread use of highly active antiretroviral therapy capable of assisting in immune system recovery and lowering the viral load in patients with HIV infection, the incidence of acquired immune deficiency syndrome (AIDS) and related ophthalmic infections has declined sharply.

Laboratory Diagnosis

Specimen Collection and Transport

Cell cultures for the isolation of *C. trachomatis* have been replaced by nucleic acid–based testing methods. Cell culture is only performed in specialized laboratories for antimicrobial susceptibility. Purulent material from the surface of the lower conjunctival sac and inner canthus (angle) of the eye is collected on a sterile swab for cultures. Both eyes should be cultured separately. Chlamydial cultures are taken with a dry calcium alginate swab and placed in a 2-SP (2-sucrose phosphate) transport medium.

For patients with keratitis, an ophthalmologist collects scrapings of the cornea with a heat-sterilized platinum spatula. For bacterial isolation, multiple inoculations with the spatula are made to blood agar, chocolate agar, an agar for the isolation of fungi, thioglycollate broth, and an anaerobic blood agar plate. Other special media may be used if indicated. Corneal specimens for culture of HSV and adenovirus are placed in viral transport media. Recently the collection of two corneal scrapes (one used for Gram stain and the other transported in brain-heart infusion medium and used for culture) was determined to provide a simple method for diagnosis of bacterial keratitis.

Cultures of endophthalmitis specimens are inoculated with material obtained by the ophthalmologist from the anterior and posterior chambers of the eye, wound abscesses, and wound dehiscence (splitting open). Lid infection material is collected on a swab in the conventional manner. For microbiologic studies of canaliculitis, material from the lacrimal canal should be transported under anaerobic conditions. Aspiration of fluid from the orbit is contraindicated in patients with orbital cellulitis. A patient history of sinusitis in association with orbital cellulitis is an indication for obtaining an otolaryngologist's assistance in the collection of material from the maxillary sinus by **antral puncture.** Blood cultures should also be obtained. Tissue biopsy is essential for the microbiologic diagnosis of mucormycosis. Because cultures are usually negative, the diagnosis is made by histologic examination.

Direct Visual Examination

All material submitted for culture should be smeared and examined directly by Gram stain or other appropriate microscopic techniques. In bacterial conjunctivitis, polymorphonuclear leukocytes predominate; in viral infection, the host cells are primarily lymphocytes and monocytes. Specimens in which *Chlamydia* is suspected can be stained immediately with monoclonal antibody conjugated to fluorescein for the detection of elementary bodies or inclusions. Using histologic stains, basophilic intracytoplasmic inclusion bodies are seen in epithelial cells. Cytologists and anatomic pathologists usually perform these tests. Direct examination of conjunctivitis specimens using histologic methods (Tzanck smear; a scraping from the lesion for collection of cells) may reveal multinucleated epithelial cells typical of herpes viral infections. However, DFA stains available for both HSV and VZV are recommended for rapid diagnosis of viral infections. In patients with keratitis, scrapings may be examined using Gram, Giemsa, periodic acid-Schiff (PAS), and methenamine silver stains. If *Acanthamoeba* or other amoebae are suspected, corneal scrapings or a corneal biopsy should be kept at room temperature (24°C to 28°C) and a direct wet preparation should be examined for motile trophozoites, and a trichrome stain should be added to the regimen. For this diagnosis, however, culture is by far the most sensitive detection method for the identification of the organism. In patients with endophthalmitis, the specimen is examined using Gram, Giemsa, PAS, and methenamine silver stains. When submitted in large volumes of fluid, ophthalmic specimens must be concentrated by centrifugation before additional studies are performed.

Nucleic Acid Testing Methods

In general, for nucleic acid testing methods, the manufacturer provides specific directions and/or specific collection vials or transport media. All collection, processing, and transport should follow the manufacturer's recommended protocols.

Other Nonculture Methods

Although acute and convalescent serologic tests for viral agents might be used in the event of epidemic conjunctivitis, they typically are not performed, because the infections are self-limited. Enzyme-linked immunosorbent assay (ELISA) tests and DFA staining are available for the detection of *C. trachomatis*. An ELISA test of aqueous humor is available for the diagnosis of *Toxocara* infection. Finally, nucleic acid–based methods have replaced most of these methods and are used for the diagnosis of viral and chlamydial keratoconjunctivitis, along with other ophthalmic infections, including uveitis.

Culture

Because of the constant washing action of the tears, the number of organisms recovered from cultures of eye infections may be relatively low. Unless the clinical specimen is obviously purulent, using a relatively large inoculum and a variety of media is recommended to ensure recovery of the etiologic agent. Conjunctival scrapings placed directly onto media yield the best results. At a minimum, blood and chocolate agar plates should be inoculated and incubated under increased carbon dioxide tension (5% to 10% CO_2). Because potential pathogens may be present in an eye without causing infection, it can be very helpful to culture both eyes. If a potential pathogen grows in cultures of the infected and the uninfected eye, the organism may not be causing the infection; however, if the organism only grows in culture from the infected eye, it is most likely the causative agent. When *M. lacunata* is suspected, Loeffler medium may prove useful; the growth of the organism often leads to proteolysis and pitting of the medium, although nonproteolytic strains may be isolated. If diphtheritic conjunctivitis is suspected, Loeffler or cystine-tellurite medium should be used. For more serious eye infections, such as keratitis, endophthalmitis, and orbital cellulitis, a reduced anaerobic blood agar plate, a medium for the isolation of fungi, and a liquid medium such as thioglycolate broth should always be included. The diagnosis of endophthalmitis typically requires a culture of the vitreous; vitreous washings typically yield positive cultures better than more invasive techniques. Invasive techniques for the collection of vitreous include either a needle aspirate or vitrectomy. A **vitrectomy** is a surgical procedure that simultaneously cuts and collects some vitreous fluid. Blood cultures are also important in serious eye infections.

Specimen cultures for *Chlamydia* and viruses should be inoculated to appropriate media from transport broth.

For *Chlamydia* isolation, cycloheximide-treated McCoy cells should be used; for viral isolation the use of human embryonic kidney, primary monkey kidney, and Hep-2 cell lines is recommended.

Ears

Anatomy

The ear is divided into three anatomic parts: the external, middle, and inner ear. Important anatomic structures are depicted in Fig. 71.4.

The middle ear is part of a continuous system including the nares, nasopharynx, auditory tube, and mastoid air spaces. These structures are lined with respiratory epithelium (e.g., ciliated cells, mucus-secreting goblet cells).

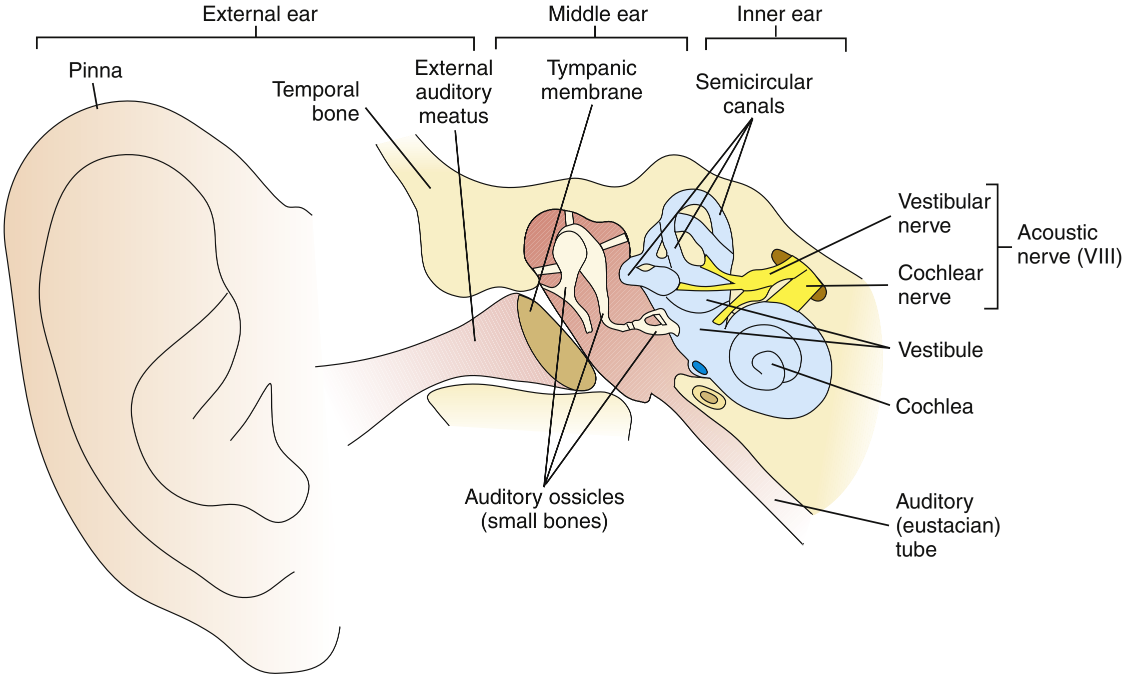
Resident Microbiota

The normal microbiota within the external ear canal is rather sparse, similar to flora of the conjunctival sac. Pneumococci *(S. pneumoniae), C. acnes, S. aureus,* and Enterobacterales are somewhat more common. *P. aeruginosa* is found on occasion. *Candida* spp. (non–*C. albicans*) are also common.

Diseases, Epidemiology, and Etiology of Disease

Otitis Externa (External Ear Infections)

Otitis externa is similar to skin and soft tissue infection. Two major types of external otitis exist: acute or chronic. **Acute external otitis** may be localized or diffuse. Acute localized disease occurs in the form of a pustule or furuncle and typically is caused by *S. aureus*. Erysipelas caused by group A streptococci may involve the external ear canal and the soft tissue of the ear. Acute diffuse otitis externa



• **Fig. 71.4** The ear. (Modified from Thibodeau GA, Patton KT. *Anatomy and Physiology*. 2nd ed., St Louis: Mosby; 1993.)

(swimmer's ear) is related to maceration (softening of tissue) of the ear from swimming or hot, humid weather. Gram-negative bacilli, particularly *P. aeruginosa*, play an important role. A severe, hemorrhagic external otitis caused by *P. aeruginosa* is difficult to treat and has occasionally been related to hot tub use.

Chronic otitis externa results from the irritation of drainage from the middle ear in patients with chronic, suppurative otitis media and a perforated eardrum. **Malignant otitis externa** is a necrotizing infection that spreads to adjacent areas of soft tissue, cartilage, and bone. If allowed to progress and spread into the central nervous system or vascular channel, a life-threatening condition may develop. *P. aeruginosa*, in particular, and anaerobes are commonly associated with this process. Malignant otitis media is seen in patients with diabetes who have blood vessel disease of the tissues overlying the temporal bone in which poor local perfusion of tissues results in an environment conducive for invasion by bacteria. On occasion, external otitis can extend into the cartilage of the ear, usually requiring surgical intervention. Certain viruses may infect the external auditory canal, the soft tissue of the ear, or the tympanic membrane; influenza A virus is a suspected, but not an established, cause. VZV may cause painful vesicles within the soft tissue of the ear and the ear canal. Viral agents such as influenza and bacterial agents are typically associated with acute otitis media (*S. pneumoniae, H. influenzae*, and *M. catarrhalis*). *Mycoplasma pneumoniae* is rarely associated with this condition.

Otitis Media (Middle Ear Infections)

In children (in whom **otitis media** is most common), pneumococci and *H. influenzae* are the usual etiologic agents in acute disease. Group A streptococci *(S. pyogenes)*, *M. catarrhalis*, *S. aureus*, gram-negative enteric bacilli, and anaerobes are also associated with middle ear infections. Viruses, chiefly respiratory syncytial virus (RSV), coronaviruses, enteroviruses, rhinoviruses, and influenza viruses, have been recovered from the middle ear fluid of children with acute or chronic otitis media. *C. trachomatis* and *M. pneumoniae* have occasionally been isolated from middle ear aspirates. Otitis media with effusion (fluid) is considered a chronic sequela of acute otitis media. A slowly growing organism, *Alloiococcus otitis*, is a pathogen that has been isolated from patients with otitis media with effusion.

Chronic otitis media yields a predominantly anaerobic flora, with *Peptostreptococcus* spp., *Bacteroides fragilis* group, *Prevotella melaninogenica* (pigmented, anaerobic, gram-negative rods), *Porphyromonas*, other *Prevotella* spp., and *Fusobacterium nucleatum* as the principal pathogens; less common are *S. aureus*, *P. aeruginosa*, *Proteus* spp., and other gram-negative facultative bacilli. Table 71.2 summarizes the major causes of ear infections.

The **mastoid** is a portion of the temporal bone (lower sides of the skull) containing the mastoid sinuses (cavities). **Mastoiditis** is a complication of chronic otitis media in which organisms find their way into the mastoid sinuses. To prevent the further spread of this infection to the central nervous system, a **mastoidectomy** is performed.

Pathogenesis

Local trauma, the presence of foreign bodies, or excessive moisture can lead to otitis externa (external ear infections).

TABLE 71.2 **Major Infectious Causes of Ear Infection**

Disease	Common Causes
Otitis externa	Acute: *Staphylococcus aureus, Streptococcus pyogenes, Pseudomonas aeruginosa;* other gram-negative bacilli
	Chronic: *P. aeruginosa;* anaerobes
Otitis media	Acute *Streptococcus pneumoniae; Haemophilus influenzae; Moraxella catarrhalis; S. pyogenes;* respiratory syncytial virus; influenza virus; coronaviruses, enteroviruses, rhinoviruses
	Chronic: Anaerobes

Note: This table is not intended to be all-inclusive for the infectious agents capable of causing ear infections.

Occasionally, an infection from the middle ear can extend by purulent drainage to the external ear.

Anatomic or physiologic abnormalities of the auditory tube can predispose individuals to develop otitis media. The auditory tube is responsible for protecting the middle ear from nasopharyngeal secretions, draining secretions produced in the middle ear into the nasopharynx, and ventilating the middle ear and equilibrating air pressure with the external ear canal. If any of these functions become compromised and fluid develops in the middle ear, infection may occur. To illustrate, if a person has a viral upper respiratory infection, the auditory tube becomes inflamed and swollen. This inflammation and swelling may, in turn, compromise the auditory tube's ventilating function, resulting in a negative, rather than a positive, pressure in the middle ear. This change in pressure can then allow for potentially pathogenic bacteria present in the nasopharynx to enter the middle ear.

Laboratory Diagnosis

Specimen Collection and Transport

Although middle ear infection, or otitis media, is usually not diagnosed by culture, culture can be used for the laboratory diagnosis of external otitis; the external ear should be cleansed with a mild germicide such as 1:1000 aqueous solution of benzalkonium chloride to reduce the numbers of contaminating skin microbiota before obtaining the specimen. Material from the ear, especially that obtained after spontaneous perforation of the eardrum or by needle aspiration of middle ear fluid (**tympanocentesis**), should be collected by an otolaryngologist, using sterile equipment. Specimens from the mastoid are generally taken on swabs during surgery, although actual bone is preferred. Specimens should be transported anaerobically.

Direct Visual Examination

Material aspirated from the middle ear or mastoid is also examined directly for bacteria and fungi. The calcofluor white or PAS stains can reveal fungal elements. Methenamine silver stains have the added efficiency of staining most bacterial and fungal organisms and several parasitic species.

Culture and Nonculture Methods

Ear specimens submitted for culture should be inoculated to blood, MacConkey, and chocolate agars. Anaerobic cultures should also be set up on those specimens obtained by tympanocentesis or those obtained from patients with chronic otitis media or mastoiditis. Because cultures of middle ear effusions are culture positive for only 20% to 30% of patients, conventional and nucleic acid–based test methods have been used to detect the common middle ear pathogens.

Sinuses

Anatomy

The sinuses, like the mastoids, are unique, air-filled cavities within the head (Fig. 71.5). The sinuses are normally sterile. These structures, as well as the eustachian tube, the middle ear, and the respiratory portion of the pharynx, are lined by respiratory epithelium. The clearance of secretions and contaminants depends on normal ciliary activity and mucous flow.

Diseases

The pathogens associated with otitis media are the same ones associated with **sinusitis**; bacteria from the nose and throat make their way to the inner ear and sinuses. Acute sinusitis usually develops during a cold or influenza illness and tends to be self-limited, lasting 1 to 3 weeks, and is usually more prevalent in winter and spring. Acute sinusitis is often difficult to distinguish from the primary illness. Symptoms include purulent nasal and postnasal discharge, a feeling of pressure over the sinus areas of the face, cough, and a nasal quality to the voice. Fever is sometimes present.

Occasionally, acute sinusitis persists and reaches a chronic state in which bacterial colonization occurs and the condition no longer responds to antibiotic treatment. Ordinarily, surgery or drainage is required for successful management. Patients with chronic sinusitis may have acute exacerbations (flare-ups). Other complications include local extension into the orbit, skull, meninges, or brain, and development of chronic sinusitis.

Pathogenesis

Most cases of acute sinusitis are believed to be bacterial complications following a viral respiratory infection. The exact mechanisms involved are unknown. About 5% to 10% of acute maxillary sinus infections result from infection originating from a dental source. The maxillary sinuses are close to the roots of the upper teeth, providing a mechanism for dental infections to extend into the sinuses. The primary

TABLE 71.3 **Major Infectious Causes of Acute Sinusitis**

Age Group	Common Causes
Young adults	*Haemophilus influenzae, Streptococcus pneumoniae, Streptococcus pyogenes, Moraxella catarrhalis*
Children	*S. pneumoniae, H. influenzae, M. catarrhalis,* rhinovirus

Note: This table is not intended to be all-inclusive for the infectious agents capable of causing sinusitis.

problems associated with the development of chronic sinusitis include inadequate drainage, impaired mucociliary clearance, and mucosal damage.

Epidemiology and Etiology of Disease

Although difficult to assess, the actual incidence of acute sinusitis parallels that of acute upper respiratory tract infections (i.e., being most prevalent in the fall through spring).

Most studies of the microbiology of acute sinusitis are associated with maxillary sinusitis, because it is the most common type and specimen collection is available through puncture and aspiration. Acute viral sinusitis is one of the most common causes of respiratory tract infection and, in most cases, resolves without treatment. However, published estimates indicate that 0.5% to 2% of cases of acute viral sinusitis in adults are complicated by bacterial sinusitis. This scenario is even more common in children. Bacterial cultures are positive in about three-fourths of patients. Studies have indicated that *S. pneumoniae* and *H. influenzae* are the major bacterial pathogens in adults with acute sinusitis; other species such as beta-hemolytic and alpha-hemolytic streptococci, *S. aureus*, and anaerobes have also been cultured but less commonly. The predominant bacterial organisms associated with chronic sinusitis include *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*; less commonly, isolated organisms include anaerobic streptococci, *Prevotella* spp., and *Fusobacterium* spp. Fungal pathogens such as *Aspergillus*, *Fusarium*, and *C. albicans* have also been identified in cases of chronic sinusitis using culture and nucleic acid–based test methods.

The major causes of acute sinusitis are summarized in Table 71.3. *M. catarrhalis* has been isolated in chronic sinusitis in children.

Laboratory Diagnosis

In most cases, a diagnosis can be made based on physical findings, history, radiograph studies, and other imaging techniques such as magnetic resonance imaging. However, if a laboratory diagnosis is needed, an otolaryngologist collects a specimen from the maxillary sinus by puncture and aspiration or during surgery. Sinus drainage is unacceptable for smear or culture, because this material will be contaminated with aerobic and anaerobic normal respiratory microbiota; sinus washings or aspirates surgically collected are the specimens of choice. Gram-stained smears and aerobic and anaerobic cultures should be performed on each specimen. Aerobic culture media should include blood, chocolate, and MacConkey agar.

Matrix-Assisted Laser Desorption Ionization Time-of-Flight Mass Spectrometry

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) may be used to identify pathogens from these infections directly from pure colony isolates. The limitations of identification, however, rely on technical expertise in sample preparation and the limitations of the current database (Chapter 7).

CASE STUDY 71.1

A 12-year-old boy complained of severe ear pain of 4 days duration. He was afebrile, but his tympanic membrane was erythematous and bleeding. The boy had been swimming a few days earlier in a local lake. His physician collected samples, which grew a gram-negative rod with a pleasant odor. The patient was given antibiotic eardrops and did well, with resolution of his symptoms.

Questions

1. What organism caused this infection?
2. How can this isolate be identified rapidly?
3. If the characteristic odor is lacking, what characteristics of the organism make it easy to identify?

Chapter Review

1. The anterior cavity of the interior space of the eyeball is filled with a clear, watery substance called:
- **a.** Vitreous humor
- **b.** Aqueous humor
- **c.** Lacrimal humor
- **d.** None of the above

2. Which of the following organisms is the causative agent for blepharitis?
- **a.** *S. aureus*
- **b.** *S. epidermidis*
- **c.** HSV
- **d.** All the above

3. One of the most serious types of eye infection requiring immediate medical attention because of the risk of corneal perforation is:
- **a.** Conjunctivitis
- **b.** Keratitis
- **c.** Endophthalmitis
- **d.** Canaliculitis

4. Which of the following organisms is commonly associated with corneal eye infection in soft and extended-wear contact users?
- **a.** *Acanthamoeba* sp.
- **b.** *Pseudomonas aeruginosa*
- **c.** *Acinetobacter*
- **d.** *S. aureus*

5. Newborns are treated with antibiotic drops immediately after birth to prevent infection by what organism?
- **a.** *C. trachomatis*
- **b.** HSV
- **c.** Group B streptococci
- **d.** *H. influenzae*

6. The part of the eye that is a white fibrous tissue is called the:
- **a.** Cornea
- **b.** Lacrimal canaliculi
- **c.** Conjunctiva
- **d.** Sclera

7. Acute inflammation of the lacrimal gland may occur during what disease(s)?
- **a.** Syphilis and leprosy
- **b.** Tuberculosis
- **c.** Varicella zoster
- **d.** Mumps and infectious mononucleosis

8. Which of the following media is used in the culture of an eye infection if the organism suspected is *M. lacunata*?
- **a.** Columbia with CNA media
- **b.** Thayer-Martin media
- **c.** Loeffler medium
- **d.** Regan-Lowe media

9. All the following organisms are normally responsible for acute localized otitis media in children except:
- **a.** *S. pneumoniae*
- **b.** *S. aureus*
- **c.** *S. pyogenes*
- **d.** *H. influenzae*

10. The components of the lacrimal apparatus contain all the following *except*:
- **a.** Lacrimal gland
- **b.** Lacrimal canaliculi
- **c.** Lacrimal duct
- **d.** Lacrimal sac

11. **True or False**

_____ Otitis media or middle ear infection is usually not diagnosed by culture.

_____ The major etiologic agent of acute sinusitis in adults is *Moraxella catarrhalis*.

_____ The most common cause of orbital cellulitis is *Staphylococcus aureus*.

_____ When culturing an eye specimen for infections caused by *Chlamydia*, cycloheximide-treated McCoy cells should be used.

_____ When examining the Gram stain from a suspected case of bacterial conjunctivitis, lymphocytes and monocytes will be the predominate cells within the sample.

_____ Aerobic gram-negative rods most often cause chronic otitis media.

_____ PCR is often the testing method used to detect middle ear pathogens, because it is more sensitive than conventional culture.

_____ Most cases of acute sinusitis are believed to be bacterial complications of the common cold.

_____ In suspected cases of sinusitis, an acceptable specimen for culture is nasal drainage.

12. Matching: *Match each term with the correct description.*

_____ bullous myringitis
_____ uveitis
_____ maceration
_____ cornea
_____ trachoma
_____ exopeptidase
_____ mastoiditis
_____ otitis externa
_____ canaliculitis
_____ dacryocystitis
_____ mucormycosis
_____ iatrogenic
_____ dacryoadenitis
_____ lacrimal
_____ endophthalmitis
_____ blepharitis

a. swimmer's ear
b. anterior portion of the sclera; clear with no blood vessels
c. infection of the iris, ciliary body, and choroid
d. toxic factor produced by *S. pneumoniae*
e. inflammation of the mastoid air cells
f. resulting from the activities of a doctor
g. infection of the lacrimal gland characterized by upper eyelid pain with erythema
h. leading cause of blindness in underdeveloped countries caused by *Chlamydia trachomatis*
i. infection of the internal area of the eyeball
j. inflammation of the eyelids
k. infection of the lacrimal sac
l. softening of tissue
m. invasive fungal infection of the eye orbit
n. inflammation of the lacrimal canal
o. painful infection of the eardrum with hemorrhagic bullae
p. pertaining to tears

13. Short Answer

(1) What culture method may help a doctor determine whether an organism isolated in an eye culture is the pathogen or just normal microbiota?
(2) What is the greatest risk factor associated with orbital cellulitis?
(3) What type of suspected eye infection requires specimen transport to the laboratory under anaerobic conditions?
(4) How does the cell culture collection of a specimen for chlamydial-suspected conjunctivitis differ from that of conjunctivitis caused by other organisms? What testing method has replaced cell culture in most laboratories?
(5) Explain the difference between acute and chronic otitis externa.
(6) Differentiate acute and chronic sinusitis.
(7) Describe the toxic factors exhibited by *S. pneumoniae* and *Pseudomonas aeruginosa* responsible for corneal destruction in keratitis.

72

Infections of the Urinary Tract

OBJECTIVES

1. Describe the anatomy and identify the structures of the male and female urinary tracts.
2. Name the organisms that colonize the urethra and are considered normal microbiota.
3. Explain how the female urinary tract anatomy may predispose females to urinary tract infections.
4. Differentiate between community-acquired urinary tract infections and hospital- and health care–associated urinary tract infections.
5. List the routes of transmission that allow bacteria to invade and cause a urinary tract infection.
6. Name the physical and chemical properties of urine that contribute to its role in the body's defense mechanism against the bacteria capable of causing urinary tract infections.
7. Explain host and microbial factors that determine whether bacteria will be able to colonize and cause a urinary tract infection.
8. Name the properties bacteria possess that predispose them to have greater pathogenicity in causing urinary tract infections.
9. Define the five major types of urinary tract infections: pyelonephritis, cystitis, urethritis, acute urethral syndrome, and asymptomatic bacteriuria.
10. Compare complicated and uncomplicated urinary tract infections.
11. Explain the collection methods for urine specimens, including clean catch midstream urine, straight catheterized urine, a suprapubic bladder aspiration, and an indwelling catheter collection.
12. Describe the urine-screening methods available to determine bacteriuria and pyuria.
13. Explain the nitrate reductase test, the leukocyte esterase test, and the catalase test regarding their urine-screening capability.
14. Name the media required for urine cultures.
15. Explain the proper methodology for plating and interpreting a quantitative urine culture.
16. Correlate signs and symptoms with the results of laboratory diagnostic procedures for the identification of the etiologic agent associated with infections of the urinary tract.

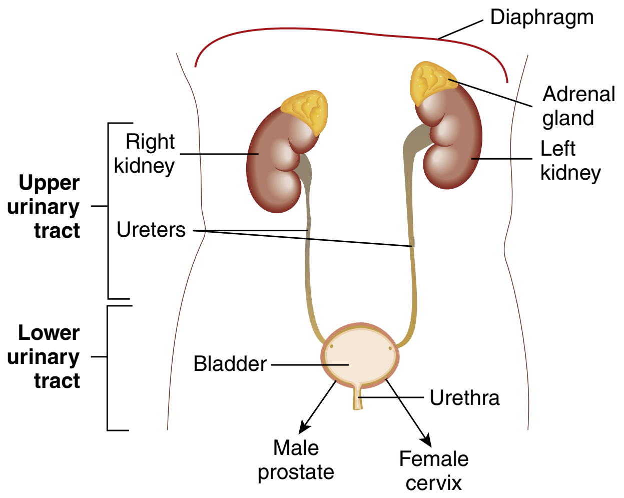
General Considerations

Anatomy

The urinary tract consists of the kidneys, ureters, bladder, and urethra (Fig. 72.1). The function of the urinary tract is to make and process urine. Urine is an ultrafiltrate of blood that consists mostly of water but also contains nitrogenous wastes, sodium, potassium, chloride, and other analytes. Urine is normally a sterile fluid. Often, **urinary tract infections (UTIs)** are characterized as being either **upper (U-UTI)** or **lower (L-UTI)** based primarily on the anatomic location of the infection: the lower urinary tract encompasses the bladder and urethra, and the upper urinary tract encompasses the ureters and kidneys. Upper UTIs affect the ureters (**ureteritis**) or the renal parenchyma (**pyelonephritis**). Lower UTIs may affect the urethra (**urethritis**), the bladder (**cystitis**), or the prostate in males (**prostatitis**). Symptomatic L-UTIs and asymptomatic U-UTIs do not rule out the possibility that the infectious agent may also be affecting the upper urinary tract.

The anatomy of the female urethra is of importance to the pathogenesis of UTIs. The female urethra is relatively short compared with the male urethra and lies in close proximity to the warm, moist, perirectal region, which is teeming with microorganisms. Because of the shorter urethra, bacteria can reach the bladder more easily in the female host; thus UTIs are primarily a disorder in females. In males, the incidence of UTIs increases after the age of 60 years, when the enlargement of the prostate interferes with the removal of urine from the bladder.

UTIs can also be classified as **uncomplicated** or **complicated.** An uncomplicated UTI indicates that there are no structural or neurological abnormalities associated with the urinary tract. A complicated UTI indicates a history of persistent, recurring infections that may be a result of physiological factors that predispose the patient to infection. This may include previous kidney failure, obstruction, kidney transplant, immunosuppression, or urinary retention.



• **Fig. 72.1** Overview of the anatomy of the urinary tract. (From Potter PH, Perry AG. *Fundamentals of Nursing*. St Louis: Mosby; 1985.)

Resident Microbiota of the Urinary Tract

The urethra has resident microbiota that colonize its epithelium in the distal portion; these organisms are lactobacilli, corynebacteria, enterococci, and coagulase-negative staphylococci (Box 72.1). Potential pathogens, including gram-negative aerobic bacilli (primarily Enterobacterales) and occasional yeasts, are also present as transient colonizers. All areas of the urinary tract above the urethra in a healthy human were previously considered sterile. There is increasing evidence that the urinary bladder may be protected by normal microbiota. Urine is typically sterile, but noninvasive methods for collecting urine must rely on a specimen that has passed through a contaminated milieu. Therefore, quantitative cultures for the diagnosis of UTIs have been used to discriminate among contamination, colonization, and infection.

• BOX 72.1 Resident Microbiota of the Urethra

Coagulase-negative staphylococci (excluding *Staphylococcus saprophyticus*)
Viridans and nonhemolytic streptococci
Lactobacilli (adult females)
Diphtheroids (*Corynebacterium* spp.)
Nonpathogenic (saprobic) *Neisseria* spp. (adult women)
Anaerobic cocci
Propionibacterium spp. (adult patients)
Commensal *Mycobacterium* spp.
Commensal *Mycoplasma* spp.
Yeasts (pregnant, adult females)

Infections of the Urinary Tract

Epidemiology

UTIs are among the most common bacterial infections that lead patients to seek medical care. It has been estimated that more than 7 million outpatient visits, 1 million visits to the emergency department, and 100,000 hospital stays every year in the United States are a result of UTIs. Approximately 60% of all females and 5% of all males will have a UTI at some time during their lives. Of note, UTIs are also the most common hospital- and health care–associated infection.

The exact prevalence of UTIs is age- and sex-dependent. During the first year of life, UTIs occur in less than 2% in males and females. The incidence of UTIs among males remains relatively low after 1 year of age and until approximately 60 years of age, when enlargement of the prostate interferes with emptying of the bladder. Extensive studies have shown that the incidence of **bacteriuria** (presence of bacteria in urine) among females 5 through 17 years of age is 1% to 3%. The prevalence of bacteriuria in females increases gradually with time to as high as 10% to 20% in older females. In females between 20 and 40 years of age who have had UTIs, as many as 50% may become reinfected within 1 year. The association of UTIs with sexual intercourse may also contribute to this increased incidence, because sexual activity increases the chances of bacterial contamination of the female urethra. Finally, because of anatomic and hormonal changes that favor the development of UTIs, the incidence of bacteriuria increases during pregnancy. These infections can lead to serious infections in both the mother and fetus. Estrogen deficiency in postmenopausal females, resulting in a decrease in normal vaginal microbiota (in particular, lactobacilli), is associated with recurrent UTIs.

UTIs are important complications of diabetes, renal disease, renal transplantation, and structural and neurologic abnormalities that interfere with urine flow. In 40% to 60% of renal transplant recipients, the urinary tract is the source for the primary occurrence of bacteremia, and in these patients, the recurrence rate is about 40%. In addition, UTIs are a leading cause of gram-negative sepsis in hospitalized patients and are the origin for about half of all health care–associated infections caused by urinary catheters.

Etiologic Agents

Community-Acquired

Escherichia coli is by far the most common cause of uncomplicated community-acquired UTIs. At the molecular level, *E. coli,* designated uropathogenic *E. coli* (UPEC), which causes UTIs, is sufficiently different from other types of *E. coli. E. coli* O25-H4 has emerged as a significant urinary tract pathogen in community-acquired infections. Other bacteria commonly isolated from patients with UTIs are *Klebsiella* spp., other Enterobacterales, *Staphylococcus saprophyticus*, and enterococci. More than 95% of uncomplicated UTIs are caused by a single bacterial species. In more complicated UTIs, particularly in recurrent infections, the relative frequency of infection caused by *Proteus*, *Pseudomonas*, *Klebsiella*, and *Enterobacter* spp. increases. In addition, community-acquired UTIs are increasingly associated with multidrug-resistant organisms such as extended beta-lactamase-resistant *E. coli.*

Hospital- and Health Care–Associated

The hospital or health care environment plays an important role in determining the organisms involved in UTIs. Hospitalized patients are most likely to be infected by antibiotic-resistant *E. coli, Klebsiella* spp., *Proteus* spp., staphylococci, enterococci, other Enterobacterales, *Pseudomonas aeruginosa*, *Enterobacter* spp., and *Candida* spp. The introduction of a foreign body into the urinary tract, especially one that remains in place for an extended period (e.g., Foley catheter), carries a substantial risk of infection, particularly if obstruction is present. Approximately 35% of all health care–associated infections are UTIs. Eighty percent of those infections are associated with the use of an indwelling catheter. In addition, highly antibiotic-resistant microorganisms such as extended-beta-lactamase–producing organisms (ESBL); Amp C beta-lactamase-, carbapenemase-producing Enterobacterales, and *Acinetobacter* spp. are increasingly identified in health care–associated UTIs. It is also not unusual to identify multiple bacterial species or infectious agents in complicated UTIs, due to repeat medical procedures and previous treatment with antibiotics. Consequently, UTI is the most common health care–associated infection in the United States, and the infected urinary tract is the most common source of bacteremia.

Miscellaneous

Other less commonly isolated agents are other gram-negative bacilli, such as *Acinetobacter* and *Alcaligenes* spp., other *Pseudomonas* spp., *Citrobacter* spp., *Gardnerella vaginalis*, *Aerococcus urinae*, and beta-hemolytic streptococci. Bacteria such as mycobacteria (predominantly in patients who are human immunodeficiency virus [HIV]-positive), *Chlamydia trachomatis, Ureaplasma urealyticum, Mycoplasma hominis, Campylobacter* spp., *Haemophilus influenzae, Leptospira,* and certain *Corynebacterium* spp. (e.g., *C. renale*) are rarely recovered from urine. In addition, *Actinobaculum schaalii* (vaginal and skin microbiota) and other *Actinobaculum* spp. may be dismissed as normal microbiota or overlooked in urine cultures because of these organisms' slow growth rate. Because renal transplant recipients are immunosuppressed, these patients not only suffer from common uropathogens but are also susceptible to opportunistic infections with unusual pathogens. A study involving renal transplant recipients showed that for culture-negative urine, amplification of regions in bacterial 16S ribosomal ribonucleic acid (rRNA) and subsequent analysis by high-performance liquid chromatography detected the presence of several known uropathogens as well as unusual agents. For example, urine specimens from renal transplant recipients or infants may contain *Listeria monocytogenes* associated with a systemic infection. *Salmonella* spp. may be recovered during the early stages of typhoid fever; their presence should be immediately reported to the physician. If anaerobes are suspected, the physician should perform a percutaneous bladder tap unless urine can be obtained from the upper urinary tract by another means (e.g., from a nephrostomy tube). Communication by the clinician to the laboratory that such an agent is suspected is important for detecting such agents. In patients with "sterile pyuria," Gram stain may reveal unusual organisms with distinctive morphology (e.g., *H. influenzae,* anaerobes). The presence of any organisms on smear that do not grow in culture is an important clue to the cause of the infection. The laboratory can then take the action necessary to optimize chances for recovery.

As previously noted, *Candida* spp. may be isolated from patients with other debilitating disease (i.e., diabetes or urinary tract obstructions) and are associated with immunosuppressive therapy or immunosuppressive conditions and antibiotic treatment. Additional fungi capable of causing systemic infections that may also be identified in urine samples include *Blastomyces dermatitidis, Coccidioides immitis, Cryptococcus neoformans,* and *Histoplasma capsulatum.* The identification of a fungal isolate in a urine specimen should be carefully evaluated and reported to the attending clinician.

In general, viruses and parasites are not usually considered urinary tract pathogens. However, adenovirus has been implicated as the causative agent in hemorrhagic cystitis in pediatric patients. *Trichomonas vaginalis* may occasionally be observed in urinary sediment, and *Schistosoma haematobium* can lodge in the urinary tract and release eggs into the urine.

Pathogenesis

Routes of Infection

Bacteria can invade and cause a UTI via three major routes: **ascending, hematogenous,** and **lymphatic pathways.** Although the ascending route is the most common course of infection in females, ascent in association with instrumentation (e.g., urinary catheterization, cystoscopy) is the most common cause of health care–associated UTIs in both sexes. For UTIs to occur by the ascending pathway, enteric gram-negative bacteria and other microorganisms that originate in the gastrointestinal tract must be able to colonize the vaginal cavity or the periurethral area. Once these organisms gain access to the bladder, they may multiply and then pass up the ureters to the kidneys. UTIs occur more often in females, at least partially because of the short female urethra and its proximity to the anus. As previously mentioned, sexual activity can increase the chances of bacterial contamination of the female urethra. In addition, postmenopausal women are more susceptible to uropathogens due to the deficiency in estrogen and the loss of protective lactobacilli in the vaginal tract.

In most hospitalized patients, UTI is preceded by urinary catheterization or other manipulation of the urinary tract. The pathogenesis of catheter-associated UTI is not fully understood. It is certain that soon after hospitalization, patients become colonized with bacteria endemic to the institution—often gram-negative aerobic and facultative bacilli carrying resistance markers. These bacteria colonize the patient's skin, gastrointestinal tract, and mucous membranes, including the anterior urethra. With the insertion of a catheter, the bacteria may be pushed along the urethra into the bladder or, with an indwelling catheter, may migrate along the track between the catheter and the urethral mucosa, gaining access to the bladder. It is estimated that approximately 10% to 30% of catheterized patients will develop **bacteriuria** (presence of bacteria in urine).

UTIs may also occur by the hematogenous, or bloodborne, route. Hematogenous spread usually occurs as a result of bacteremia. Any systemic infection can lead to seeding of the kidney, but certain organisms, such as *Staphylococcus aureus* or *Salmonella* spp., are particularly invasive. Although most infections involving the kidneys are acquired through the ascending route, yeast (usually *Candida albicans*), *Mycobacterium tuberculosis, Salmonella* spp., *Leptospira* spp., or *S. aureus* in the urine may indicate pyelonephritis acquired via hematogenous spread or the descending route. Hematogenous spread accounts for less than 5% of UTIs and rarely occurs with gram-negative bacilli.

Finally, increased pressure on the bladder can cause lymphatic flow into the kidneys, resulting in UTI. However, evidence for the significance of this potential route is insufficient, indicating that the ascending route remains the major mechanism for the development of UTI.

The Host-Pathogen Relationship

Many individuals (females) are colonized in the vaginal or periurethral area with organisms originating from the gastrointestinal tract, yet they do not develop urinary infections. Whether an organism is able to colonize and then cause a UTI is determined in large part by a complex interplay of host and microbial factors.

In most cases, the host defense mechanisms can eliminate the organisms. Urine itself is inhibitory to some of the urethral microbiota, such as anaerobes. In addition, if urine has a low pH, high or low osmolality, high urea concentration, or high organic acid content, even organisms capable of growth in the urinary tract may be inhibited. If bacteria do gain access to the bladder, the constant flushing of contaminated urine from the body either eliminates bacteria or maintains their numbers at low levels. Clearly, any interference with the act of normal voiding, such as mechanical obstruction resulting from kidney stones or strictures, will promote the development of UTI. Also, the bladder mucosal surface has antibacterial properties. If the infection is not eradicated, the site of infection remains in the superficial mucosa; deep layers of the bladder are rarely involved.

In addition to the previously described host defenses, a valvelike mechanism at the junction of the ureter and bladder prevents the reflux (backward flow) of urine from the bladder to the upper urinary tract. Therefore, if the function of these valves is inhibited or compromised in any way, such as by obstruction or congenital abnormalities, urine reflux provides a direct route for organisms to reach the kidney. Hormonal changes associated with pregnancy and their effects on the urinary tract increase the chance for urine reflux to the upper urinary tract.

Activation of the host immune response by uropathogens also plays a key role in fending off infection. For example, bacterial contact with urothelial cells initiates an immune response via a variety of signaling pathways. Bacterial lipopolysaccharide (LPS; Chapter 2) activates host cells to ultimately release cytokines such as tumor necrosis factor and interferon-gamma. In addition, bacteria can activate the complement cascade, leading to the production of biologically active components such as opsonins, as well as augment the host's adaptive immune response. Host factors that lead to host susceptibility or resistance to uropathogens have been identified. For example, a glycoprotein synthesized exclusively by epithelial cells in a specific anatomic location in the kidney, referred to as **Tamm-Horsfall protein (THP)** or **uromodulin,** serves as an antiadherence factor by binding to *E. coli*–expressing type 1 fimbriae (discussed later). **Defensins,** a group of small antimicrobial peptides, are produced by a variety of host cells such as macrophages, neutrophils, and cells in the urinary tract and attach to the bacterial cell, eventually causing the organism's death.

Although many microorganisms can cause UTIs, most cases are a result of infection by a few organisms. To illustrate, only a limited number of serogroups of *E. coli* (01, 02, 04, 06, 07, 08, 075, 0150, 018ab) cause a significant proportion of UTIs. Numerous investigations indicate that UPEC possesses virulence factors that enhance their ability to colonize and invade the urinary tract. Some of these virulence factors include increased adherence to vaginal and uroepithelial cells by bacterial surface structures (adhesins), pili (P [PAP] type 1), and multiple types of fimbriae; the production of alpha-hemolysin (inhibits the production of protective cytokines), cytotoxic necrotizing factor (CNF), an autotransported protease (Sat), aerobactin (iuc), and a siderophore receptor (iroN); and resistance to serum-killing activity. Also, genome sequences of UPEC strains have been determined, indicating that several potential virulence factor genes associated with the acquisition and development of UTIs are encoded on pathogenicity islands (e.g., hemolysins and *E. coli* P fimbriae). By definition, pathogenicity islands (Chapter 3) contain genes that are associated with virulence and are absent from avirulent (not typically found in fecal strains) or less virulent strains of the same species. UPEC strains are a major cause of community-acquired UTIs.

The importance of adherence in the pathogenesis of UTIs has also been demonstrated with other species of bacteria. Once introduced into the urinary tract, *Proteus* strains appear to be uniquely suited to cause significant disease in the urinary tract. Data indicate that these strains can facilitate their adherence to the mucosa of kidneys. Also, *Proteus* is able to hydrolyze urea via urease production. The species *Proteus mirabilis* accounts for approximately 77% of the urinary isolates. Hydrolysis of urea results in an increase in urine pH that is directly toxic to kidney cells and stimulates the formation of kidney stones. Similar findings have been made with *Klebsiella* spp. *S. saprophyticus* also adheres better to uroepithelial cells than *S. aureus* or *S. epidermidis.*

Other bacterial characteristics may be important in the pathogenesis of UTIs. Motility may be important for organisms to ascend to the upper urinary tract against the flow of urine and cause pyelonephritis. Some organisms demonstrate greater production of capsular K antigen (K1, K5, and K12); this antigen protects bacteria from being phagocytized.

Finally, despite numerous host defenses and even antibiotic treatments that can effectively sterilize the urine, a significant proportion of patients have recurrent UTIs. Studies show that uropathogens can invade superficial epithelial cells in the bladder and replicate, forming large foci of intracellular organisms. This invasion of bladder epithelial cells triggers the host immune response, which in turn causes the superficial cells to exfoliate within hours after infection. Although this exfoliation is considered a host defense mechanism by eliminating infected cells, intracellular organisms can reemerge from the bladder epithelial cells and invade the underlying, new superficial layer of epithelial cells, consequently persisting within the urinary tract. It has been reported that intracellular bacteria mature into numerous, large protrusions on the bladder surface they referred to as "pods." This bacterial organization—in which the intracellular bacteria are embedded in a fibrous, polysaccharide-rich matrix resembling that of a biofilm—may help further explain the persistence of bladder infections despite strong host defenses.

Types of Infection and Their Clinical Manifestations

UTI encompasses a broad range of clinical entities that differ in terms of clinical presentation, degree of tissue invasion, epidemiologic setting, and requirements for antibiotic therapy. There are several types of UTIs: urethritis, ureteritis, asymptomatic bacteriuria, cystitis, the urethral syndrome, and pyelonephritis. Uncomplicated infections occur primarily in otherwise healthy females and occasionally in male infants and adolescent and adult males. Most uncomplicated infections respond readily to antibiotic agents to which the etiologic agent is susceptible. Complicated infections occur in both sexes. In general, individuals who develop complicated infections often have certain risk factors. Some of these risk factors are listed in Box 72.2. In general, complicated infections are more difficult to treat and have greater morbidity (e.g., kidney damage, bacteremia) and mortality compared with uncomplicated infections. UTIs identified in pregnant women, men, children, and hospitalized patients or patients in other health care–associated settings (e.g., cancer outpatient clinics) may be considered complicated infections. The organisms associated with these infections are commonly highly resistant to many antimicrobials.

• BOX 72.2 Risk Factors Associated With Complicated Urinary Tract Infections

Underlying diseases that predispose the kidney to infection (e.g., diabetes, sickle cell anemia)
Kidney stones
Structural or functional abnormalities of the urinary tract (e.g., a tipped bladder)
Indwelling urinary catheters

The clinical presentation of UTIs may vary, ranging from asymptomatic infection to pyelonephritis (infection of the kidney and its pelvis). Some UTI symptoms may be nonspecific, and the symptoms of lower UTIs may be considerably similar to those of upper UTIs.

Urethritis

Symptoms associated with urethritis (infection of the urethra), **dysuria** (painful or difficult urination), and frequency are similar to those associated with other lower UTIs. Urethritis is a common infection. Because *C. trachomatis, Neisseria gonorrhoeae,* and *T. vaginalis* are common causes of urethritis and considered to be sexually transmitted, urethritis is discussed as a sexually transmitted disease in Chapter 73.

Ureteritis

Inflammation or infection within the ureters (ureteritis) is considered in combination with kidney infections. UTI within the ureters indicates that organisms have begun or are in the process of ascending into the kidneys and should be treated similarly to prevent further infection.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria or **asymptomatic UTI** is the isolation of a specified quantitative count of bacteria in an appropriately collected urine specimen obtained from a person without symptoms or signs of urinary infection. Asymptomatic bacteriuria is common, but its prevalence varies widely with age, gender, and the presence of genitourinary abnormalities or underlying diseases. For example, the prevalence of bacteriuria increases with age in healthy females from as low as about 1% among school-age females to at least 20% among females 80 years of age or older living in the community, whereas bacteriuria is rare in healthy young males. Because its clinical significance was controversial (asymptomatic bacteriuria precedes UTI but does not always lead to asymptomatic infection), guidelines have been published for the diagnosis and treatment of asymptomatic bacteriuria in adults older than 18 years of age. The foundation of these guidelines rests on the premise that screening of asymptomatic subjects for bacteriuria is appropriate if bacteriuria has adverse outcomes that can be prevented by antimicrobial therapy. Thus, screening and treatment for asymptomatic bacteriuria are recommended for pregnant females (because of the risk of progression to severe symptomatic UTI and possible harm to the fetus), males undergoing transurethral resection of the prostate, and individuals undergoing urologic procedures for which mucosal bleeding is anticipated. In contrast, screening for or treatment of asymptomatic bacteriuria is not recommended for premenopausal, nonpregnant females; diabetic females;

older persons living in the community; older institutionalized adults; persons with spinal cord injury; or catheterized patients while the catheter is in place.

Cystitis

Typically, patients with cystitis (infection of the bladder) complain of dysuria, frequency, and urgency (compelling need to urinate). These symptoms are a result not only of inflammation of the bladder but also of multiplication of bacteria in the urine and urethra. Often, there is tenderness and pain over the area of the bladder. In some individuals, the urine is grossly bloody. The patient may note urine cloudiness and a bad odor. Because cystitis is a localized infection, fever and other signs of systemic illness are usually not present.

Acute Urethral Syndrome

Another UTI is **acute urethral syndrome.** Patients with this syndrome are primarily young, sexually active females, who experience dysuria, frequency, and urgency but yield fewer organisms than 10^5 colony-forming units of bacteria per milliliter (CFU/mL) urine on culture. The criterion of greater than 10^5 CFU/mL of urine is highly indicative of infection in most patients with UTIs. Almost 50% of all females who seek medical attention for complaints of symptoms of acute cystitis fall into this group. Although *C. trachomatis* and *N. gonorrhoeae* urethritis, anaerobic infection, genital herpes, and vaginitis account for some cases of acute urethral syndrome, most of these females are infected with organisms identical to those that cause cystitis but in numbers less than 10^5 CFU/mL of urine. A cutoff of 10^2 CFU/mL, rather than 10^5 CFU/mL, must be used for this group of patients, but concomitant pyuria (presence of eight or more leukocytes per cubic millimeter on microscopic examination of uncentrifuged urine) must also be present. Approximately 90% of these females have pyuria, an important discriminatory feature of infection.

Pyelonephritis

Pyelonephritis refers to inflammation of the kidney parenchyma, calices (cup-shaped division of the renal pelvis), and pelvis (upper end of the ureter that is located inside the kidney) and is usually caused by bacterial infection. Pyelonephritis may appear as an acute or chronic condition. Acute pyelonephritis presents with enlarged kidneys that contain surface abscesses. Chronic pyelonephritis presents with scarring on one or both kidneys and interstitial fibrosis on the pelvic wall. An inflammatory infiltrate of white blood cells, predominantly lymphocytes, is typically present. In addition, the tubules in the kidneys may either be dilated or constricted and contain **colloid casts** (crystalized mucous secretions). The typical clinical presentation of an upper UTI includes fever and flank (lower back) pain and, frequently, lower tract symptoms (frequency, urgency, and dysuria). Patients can also exhibit systemic signs of infection such as vomiting, diarrhea, chills, increased heart rate, and lower abdominal pain. Of significance, 40% of patients with acute pyelonephritis are bacteremic. Acute papillary necrosis of one or more renal pyramids (cone-shaped tissue) may occur as a complication associated with pyelonephritis.

Urosepsis

Approximately 25% of sepsis cases (severe blood infection) are a result of **urosepsis,** a systemic infection that may develop from community-, hospital-, or health care–associated UTIs. Urosepsis is defined as evidence of a UTI and two or more additional signs including an elevated temperature (>38°C), an elevated heart rate (>90 beats/min), an increased respiratory rate (>20 breaths/min or a PCO_2 of <32 mm Hg), or an abnormal white blood cell count (>12,000/mm^3, <4000/mm^3, or >10% neutrophilic band forms). Early diagnosis and treatment of UTIs are essential in preventing urosepsis.

Laboratory Diagnosis of Urinary Tract Infections

As previously mentioned, because noninvasive methods for collecting urine must rely on a specimen that has passed through a contaminated milieu, quantitative cultures for the diagnosis of UTI are used to discriminate between contamination, colonization, and infection. Refer to Table 5.1 for a quick reference for collecting, transporting, and processing urinary tract specimens.

Specimen Collection

Prevention of contamination by normal vaginal, perineal, and anterior urethral microbiota is the most important consideration for the collection of a clinically relevant urine specimen.

Clean-Catch Midstream Urine

The least invasive and preferred routine collection procedure, the clean-catch midstream urine specimen collection, must be performed carefully for optimal results, especially with female patients. Good patient education is essential. Guidelines for proper specimen collection should be prepared on a printed card (bilingual, if necessary), with the procedure clearly described and preferably illustrated to help ensure patient compliance. The patient should be instructed to wash their hands before cleaning the periurethral area, wiping from front to back three times, each time with a clean sterile gauze pad soaked with a mild detergent to prevent contamination. Of importance, the patient should also be instructed to rinse well with two or more sponges soaked in sterile distilled water to remove the detergent, which may be bacteriostatic. Once cleansing is completed, the patient should retract the labial folds or glans penis, begin to void, and then collect a midstream urine sample. Studies show that uncleansed, first-void specimens from males are as sensitive as (but less specific than) midstream urine specimens. Sterile bags may be used for infants and children.

Straight Catheterized Urine

Although slightly more invasive, urinary catheterization provides a method for the collection of uncontaminated urine from the bladder in uncooperative patients or patients unable to void because of other underlying physiologic conditions. Either a physician or another trained health professional performs this procedure. Risk exists, however, that urethral organisms will be introduced into the bladder with the catheter.

Suprapubic Bladder Aspiration

After preparation of the skin, urine is withdrawn directly into a syringe through a percutaneously inserted needle during **suprapubic bladder aspiration,** thereby ensuring a contamination-free specimen. The bladder must be full before the procedure is performed. This collection technique may be indicated in certain clinical situations, such as pediatric practice, when urine is difficult to obtain. If good aseptic techniques are used, this procedure can be performed with little risk in premature infants, neonates, small children, and pregnant women and other adults with full bladders.

Indwelling Catheter

Patients who are housed in hospitals and long-term care facilities and those treated in other health care–associated settings such as outpatient clinics for cancer and transplant patients are more frequently required to use indwelling urinary catheters. These patients are very likely to develop bacteriuria, which predisposes them to more severe infections. Specimen collection from patients with indwelling catheters requires scrupulous aseptic technique. Health care workers who manipulate a urinary catheter in any way should wear gloves. The catheter tubing should be clamped off above the port to allow the collection of freshly voided urine. The catheter port or wall of the tubing should then be cleaned vigorously with 70% ethanol, and urine should be aspirated via a needle and syringe; the integrity of the closed drainage system must be maintained to prevent the introduction of organisms into the bladder. Specimens obtained from the collection bag are inappropriate, because organisms can multiply there, obscuring the true relative numbers. Cultures should be obtained when patients are ill; routine monitoring does not yield clinically relevant data.

Specimen Transport

Because it is an excellent supportive medium for the growth of most bacteria, urine must be immediately refrigerated or preserved. Bacterial counts in refrigerated (4°C) urine remain constant for as long as 24 hours. Urine transport tubes (BD Urine Culture Kit [Becton Dickinson Vacutainer Kits, Franklin Lakes, NJ]) containing boric acid, sodium borate, and sodium formate have been shown to preserve bacteria without refrigeration for as long as 48 hours when more than 10^5 CFU/mL (100,000 organisms per milliliter) are present in the initial urine specimen. The system may inhibit the growth of certain organisms, and it must be used with a minimum of 3 mL of urine. Boric acid products preserve bacterial viability in urine in the absence of antibiotics. For patients from whom colony counts of organisms of less than 100,000/mL might be clinically significant, plating within 2 hours of collection is recommended. The kit provides a convenient method for preserving and transporting urine from remote areas where refrigeration is not practical.

Screening Procedures

As many as 60% to 80% of all urine specimens received for culture by the acute care medical center laboratory may contain no etiologic agents of infection or contain only contaminants. Procedures developed to quickly identify those urine specimens that will be negative on culture and circumvent excessive use of media, technical staff, and the overnight incubation period are discussed in this section. A reliable screening test for the presence or absence of bacteriuria provides physicians important same-day information that a conventional urine culture may take a day or longer to provide. Many screening methods have been advocated for use in detecting bacteriuria and/or pyuria.

Red blood cells or erythrocytes identified in the urine, **hematuria,** may also indicate UTI, but this occurs in a variety of other physiologic disorders. White blood cell casts in urine are strong evidence of pyelonephritis but can also be associated with renal disease in the absence of infection. In addition, elevated levels of protein (<2 g in 24 hours) in a urine sample may also indicate a UTI.

Gram or Methylene Blue Stain

A differential Gram stain or basic nondifferential methylene blue stain of urine is an easy, inexpensive means to provide immediate information as to the nature of the infecting organism (bacteria or yeast) to guide empiric therapy. After a drop of well-mixed urine is allowed to air dry, the smear is fixed, stained, and examined under oil immersion (1000×) for the presence of 1 or 5 bacteria per oil immersion field (OIF). The performance characteristics of the urine Gram stain are not well defined, in that different criteria have been used to define a positive result (1 or 5 bacteria per OIF). Using either 1 or 5 bacteria/OIF has a sensitivity of 96% and 95%, respectively, and a specificity of 91% when correlated with significant bacteriuria (>10^5 CFU/mL—extrapolated as one bacterium per microscopic field in an uncentrifuged sample). The absence of bacteria in a stained sediment from a centrifuged sample (5 minutes at 2000 rpm) indicates the probability that the specimen contains less than 10^4 bacteria/mL. The Gram stain should not be relied on for detecting polymorphonuclear leukocytes in urine, because leukocytes deteriorate quickly in urine that is not fresh or not adequately preserved. Many microbiologists have not adopted Gram stain examination of urine specimens because of its unreliability in detecting lower yet clinically significant numbers of organisms and because of its labor intensity. If used, urine Gram stain should be limited to patients with acute pyelonephritis, patients with invasive

UTIs, or other patients for whom immediate information is necessary for appropriate clinical management.

Pyuria

Pyuria (10 leukocytes/mm^3, using a hematocytomer from a clean-catch midstream specimen) is the hallmark of inflammation, and the presence of polymorphonuclear neutrophils (PMNs) can be detected and enumerated in uncentrifuged specimens. This method of screening urine correlates well with the number of PMNs (neutrophils) excreted per hour, the best indicator of the host's state. Patients with more than 300,000 PMNs excreted into the urine per hour are likely to have a current infection. The standard urinalysis (usually completed in the laboratory hematology or chemistry sections) includes an examination of the centrifuged sediment of urine for enumeration of PMNs, results of which do not correlate well with either the PMN excretion rate or the presence of infection. Pyuria also can be associated with other clinical diseases, such as vaginitis, and therefore is not specific for UTIs.

Indirect Indices

Screening tests commonly detect bacteriuria or pyuria by examining for the presence of bacterial enzymes or PMN enzymes rather than the organisms or PMNs themselves.

Nitrate Reductase (Griess) Test

The nitrate reductase (Griess) test looks for the presence of urinary nitrite, an indicator of UTI. Nitrate-reducing enzymes that are produced by the most common urinary tract pathogens reduce nitrate to nitrite. This test has been incorporated onto a urinary dipstick that also tests for leukocyte esterase—an enzyme produced by PMNs (discussed next). Liquid-chromatography tandem mass spectrometry (LC-MS/MS) has been used to screen urine for the presence of nitrate and nitrite for the diagnosis of UTIs. This test is not sensitive to variations in urine chemistry and has a demonstrated specificity (91%) and sensitivity (95%), which is greater than using the nitrate reductase test.

Leukocyte Esterase Test

As previously mentioned, evidence of a host response to infection is the presence of PMNs in the urine. Because inflammatory cells produce leukocyte esterase, a simple, inexpensive, and rapid method that measures this enzyme has been developed. Studies have shown that leukocyte esterase activity correlates with hemocytometer chamber counts. The nitrate reductase and leukocyte esterase tests have been incorporated into the urinary dipstick. Numerous manufacturers sell these strips commercially, and the strips are one of the most widely used enzymatic tests. Although the sensitivity of the combination strip is higher than either test alone, the sensitivity of this combination screening is not great enough to recommend its use as a standalone test in most circumstances. Of note, the leukocyte esterase test is not sensitive enough for determining pyuria in patients with acute urethral syndrome.

Catalase

The Accutest Uriscreen (JANT Pharmacal Corp., Encino, CA) is another rapid urine-screening system based on the detection of catalase present in human somatic cells and in most bacterial species that commonly cause UTIs except for streptococci and enterococci. Approximately 1.5 to 2 mL of urine is added to a tube containing dehydrated substrate. Hydrogen peroxide is added to the urine, and the solution is mixed gently. The formation of bubbles above the liquid surface is interpreted as a positive test. Visible results are available in approximately 2 minutes.

Automated and Semiautomated Systems

Automated screening systems offer a large throughput with minimal labor and a rapid turnaround time compared with conventional cultures.

Various automated or semiautomated urine-screening systems are commercially available, such as the Iris Urinalysis System (Beckman-Coulter, Inc., Brea, CA), and can analyze a urine or body fluid sample in one instrument. The instrument analyzes both the microscopic components and the urine chemistries by combining technology of both types of analyzers into one automated system. The Iris System uses a flow-imaging microscopy method to capture individual images of each particle identified in the specimen and then classifies the particle using Auto-Particle Recognition (APP) software. Siemens Medical Solutions USA, Inc. (Malvern, PA) manufactures a wide range of CLINITEK automated/semiautomated urine analyzers that include point-of-care to high-throughput walkaway instruments. In addition, the Sysmex UN-2000 (Lincolnshire, IL) uses flow cytometry and specific fluorescent dyes for the physical and chemical identification of organisms and other particles in urine samples. Various studies have indicated that automated urinalysis instrumentation has demonstrated limitations and continue to recommend manual microscopic analysis of urine samples for the diagnosis of UTI.

General Comments Regarding Screening Procedures

In general, screening methods are insensitive at levels below 10^5 CFU/mL. Therefore, they are not acceptable for urine specimens collected by suprapubic aspiration, catheterization, or cystoscopy. Screening methods may also fail to detect a significant number of infections in symptomatic patients with low colony counts (10^2 to 10^3 CFU/mL), such as young, sexually active females with acute urethral syndrome. Further complicating the laboratory's decision as to whether to adopt a screening method is whether screening results will be used to rule out infection in asymptomatic patients. Under these circumstances, testing for pyuria is essential.

Therefore, given the importance of the 10^2 CFU/mL count and the PMN count, no screening test should be used indiscriminately. Selecting a screening method largely depends on the laboratory and the patient population being served by the laboratory. For example, there will be a cost advantage in screening urine in laboratories that receive many culture-negative specimens. On the other hand, urine from patients with symptoms of UTI plus a selected group expected to have asymptomatic bacteriuria should be cultured. For example, patients in their first trimester of pregnancy should be cultured, because these patients might appear asymptomatic but have a covert infection and become symptomatic later; UTIs in pregnant females may lead to pyelonephritis and the likelihood of a premature birth. Other situations in which patients with no symptoms of UTI might be cultured include the following:

- Bacteremia of unknown source
- Urinary tract obstruction
- Follow-up after removal of an indwelling catheter
- Follow-up of previous therapy

Other factors that must be considered when selecting a rapid urine screen include accuracy, ease of test performance, reproducibility, turnaround time, and whether bacteriuria or pyuria is detected.

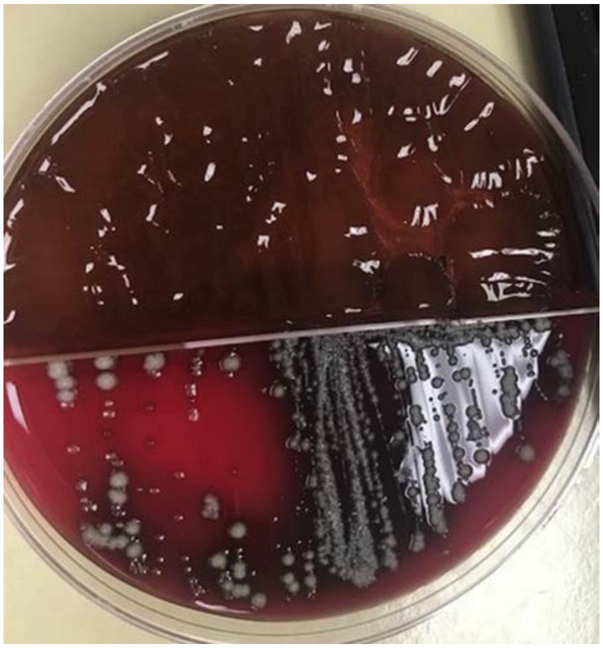
Urine Culture

Inoculation and Incubation of Urine Cultures

Once it has been determined that a urine specimen should be cultured for isolation of the common agents of UTI, a measured amount of urine is inoculated to each of the appropriate media. The urine should be mixed thoroughly before plating. The plates can be inoculated using a calibrated loop designed to deliver a known volume, either 0.01 or 0.001 mL of urine. These loops, made of platinum, plastic, or other material, can be obtained from laboratory supply companies.

The calibrated loop that delivers the larger volume of urine (0.01 mL) is recommended to detect lower numbers of organisms in certain specimens. For example, urine collected from catheterization, nephrostomies, ileal conduits, and suprapubic aspirates should be plated with the larger calibrated loop. The communication of pertinent clinical history to the laboratory is essential so that appropriate processing can be performed.

The choice of media to inoculate depends on the patient population served and the microbiologist's preference. The use of a 5% sheep blood agar plate and a MacConkey agar plate allows the detection of most gram-negative bacilli, staphylococci, streptococci, and enterococci. To save cost and somewhat streamline culture processing, many laboratories use an agar plate split in half (biplate); one side contains 5% sheep blood agar and the other half contains MacConkey or Eosin Methylene Blue agar (Fig. 72.2).

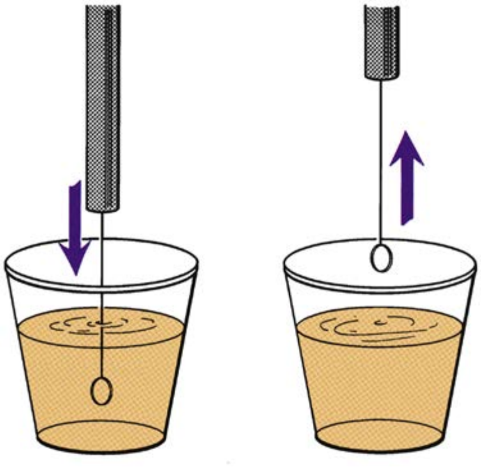


• **Fig. 72.2** *Cronobacter sakazakii* isolated from a urinary sample on a 5% sheep blood agar/eosin methylene blue biplate.

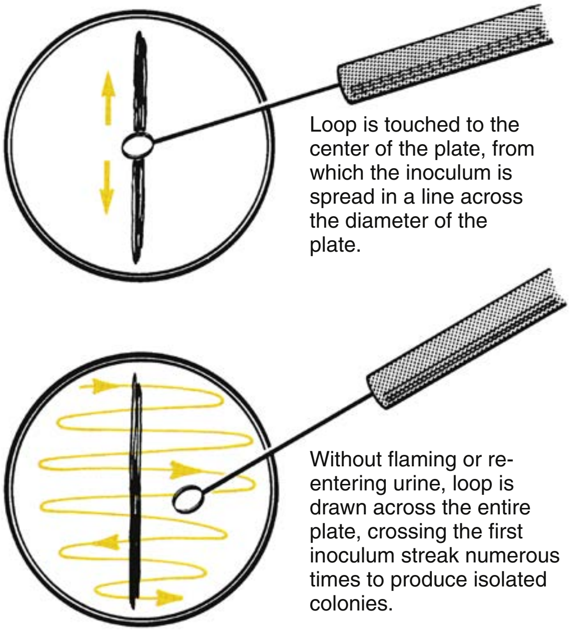
In some circumstances, enterococci and other streptococci may be obscured by heavy growth of Enterobacterales. Because of this possibility, some laboratories add a selective plate for gram-positive organisms, such as Columbia colistin-nalidixic acid agar (CNA) or Enterococcosel Agar (Bile Esculin Azide Agar, Becton-Dickinson, Sparks, MD). Although some discriminatory capability may be added, cost is also added to the procedure. In addition to increased cost, inclusion of plated media selective for gram-positive organisms generally provides no or limited additional information. Many European laboratories use cystine-lactose electrolyte-deficient (CLED) agar. CLED agar does not contain sodium chloride, inhibiting the characteristic swarming of *Proteus* spp., but still supports adequate growth of most common urinary pathogens. In recent years, chromogenic media have been introduced and become commercially available from several manufacturers, allowing more specific direct detection and differentiation of urinary tract pathogens on primary plates, such as BD CHROMagar (Becton Dickson, Heidelberg, Germany). This medium uses enzymatic reactions to identify *E. coli* and *Enterococcus* without additional confirmatory testing from urine specimens and provides presumptive identification of *S. saprophyticus, Streptococcus agalactiae, Klebsiella-Enterobacter-Serratia,* and the *Proteus-Morganella-Providencia* groups.

Before inoculation, urine is mixed thoroughly, and the top of the container is then removed. The calibrated loop is inserted vertically into the urine in a cup. Otherwise, more than the desired volume of urine will be taken up, potentially affecting the quantitative culture result (Fig. 72.3). A widely used method is described in Evolve Procedure 72.1. Once inoculated, the plates are streaked to obtain isolated colonies (Fig. 72.4).

Once plated, urine cultures are incubated overnight at 35°C. Incubation for a minimum of 24 hours is typically necessary to detect uropathogens. Thus, some specimens inoculated late in the day cannot be read accurately the next morning. These cultures should either be reincubated until the next day or interpreted later in the day when a full 24-hour incubation has been completed.



• **Fig. 72.3** Method for inserting a calibrated loop into urine to ensure that the proper amount of specimen adheres to the loop.



Loop is touched to the center of the plate, from which the inoculum is spread in a line across the diameter of the plate.
Without flaming or re-entering urine, loop is drawn across the entire plate, crossing the first inoculum streak numerous times to produce isolated colonies.

• **Fig. 72.4** Method for streaking with calibrated urine loop to produce isolated colonies and countable colony-forming units.

Interpretation of Urine Cultures

As previously mentioned, UTIs may be completely asymptomatic, produce mild symptoms, or cause life-threatening infections. Of importance, the criteria most useful for microbiologic assessment of urine specimens is dependent not only on the type of urine submitted (e.g., voided, straight catheterization) but the clinical history of the patient (e.g., age, sex, symptoms, antibiotic therapy).

One major problem in interpreting urine cultures arises because urine cultures collected by the voided technique may be contaminated with normal microbiota, including Enterobacterales. Determining what colony count represents true infection from contamination is of utmost importance and is related to the patient's clinical presentation. Several studies have proposed the use of different cutoffs in colony counts based on clinical presentation; an example of one such set of guidelines is given in Table 72.1.

Ideally, the clinician caring for the patient should provide the laboratory with enough clinical information to allow specimens from different patient populations to be identified. These specimens could then be selectively processed using the guidelines in Table 72.1. However, because microbiology laboratories frequently receive little or no clinical information about patients, questions have been raised as to whether these cutoffs are practical and realistic for routine laboratory use. Further complicating urine culture interpretation is the increasing difficulty in distinguishing between infection and contamination as the criterion for a positive culture is lowered from 10^5 CFU/mL to 10^2 CFU/mL. Because of these issues, many laboratories establish their own interpretative criteria for urine cultures based on the type of urine submitted (e.g., clean-catch midstream, catheterized, or surgically obtained specimens such as suprapubic aspirates). Variations in interpretative guidelines occur from one laboratory to another, but some generalities can be made; these are listed in Table 72.2. Some examples of urine culture results are shown in Fig. 72.5 to illustrate some of these interpretations. See the Evolve site for a semiquantitative procedure for the inoculation of urine cultures.

In addition to the previously described guidelines, a pure culture of *S. aureus* is significant regardless of the number of CFUs, and antimicrobial susceptibility tests are performed. The presence of yeast in any number is reported to physicians, and pure cultures of yeast may be identified to the species level. In all urine, regardless of the extent of final workup, all isolates should be enumerated (e.g., three different organisms present at 10^3 CFU/mL), and those present in numbers greater than 10^4 CFU/mL should be described morphologically (e.g., non–lactose fermenting gram-negative rods).

Visit the Evolve site for a complete list of procedures, review questions, and case studies.

TABLE 72.1 Criteria for Classification of Urinary Tract Infections by Clinical Syndrome

Category	Clinical	Laboratory Results
Acute, uncomplicated UTI in females	Dysuria, urgency, frequency, suprapubic pain No urinary symptoms in last 4 weeks before the current episode No fever or flank pain	≥ 10 WBC/mm^3 $\geq 10^3$ CFU/mL uropathogens[a] in CCMS urine
Acute, uncomplicated pyelonephritis	Fever, chills Flank pain on examination Other diagnoses excluded No history or clinical evidence of urologic abnormalities	≥ 10 WBC/mm^3 $\geq 10^4$ CFU/mL uropathogens in CCMS urine
Complicated UTI and UTI in males	Any combination of symptoms listed above. One or more factors associated with complicated UTI[b]	≥ 10 WBC/mm^3 $\geq 10^5$ CFU/mL uropathogens in CCMS urine
Asymptomatic bacteriuria: female patients	No urinary symptoms	$\pm > 10$ WBC/mm^3 $\geq 10^5$ CFU/mL in two CCMS cultures >24 h apart
Asymptomatic bacteriuria: male patients	No urinary symptoms	$\pm > 10$ WBC/mm^3 $\geq 10^3$ CFU/mL (suggestive) $\geq 10^5$ CFU/mL (definitive) in one CCMS

[a] Uropathogens: Organisms that commonly cause UTIs.

[b] Factors associated with complicated UTI include any UTI in a male patient, indwelling or intermittent urinary catheter, more than 100 mL of postvoid residual urine, obstructive uropathy, urologic abnormalities, azotemia (excess urea in the blood, even without structural abnormalities), and renal transplantation.

CCMS, Clean-catch midstream urine; *CFU,* colony-forming unit; *UTI,* urinary tract infection; *WBC,* white blood cells.

Data from Stamm WE. Criteria for the diagnosis of urinary tract infection and for the assessment of therapeutic effectiveness. *Infection* 20(suppl 3):S151, 1992; and Bennett J, Dolin R, Blaser M. *Principles and Practice of Infectious Diseases*. 8th ed. Philadelphia: Elsevier-Saunders; 2015.

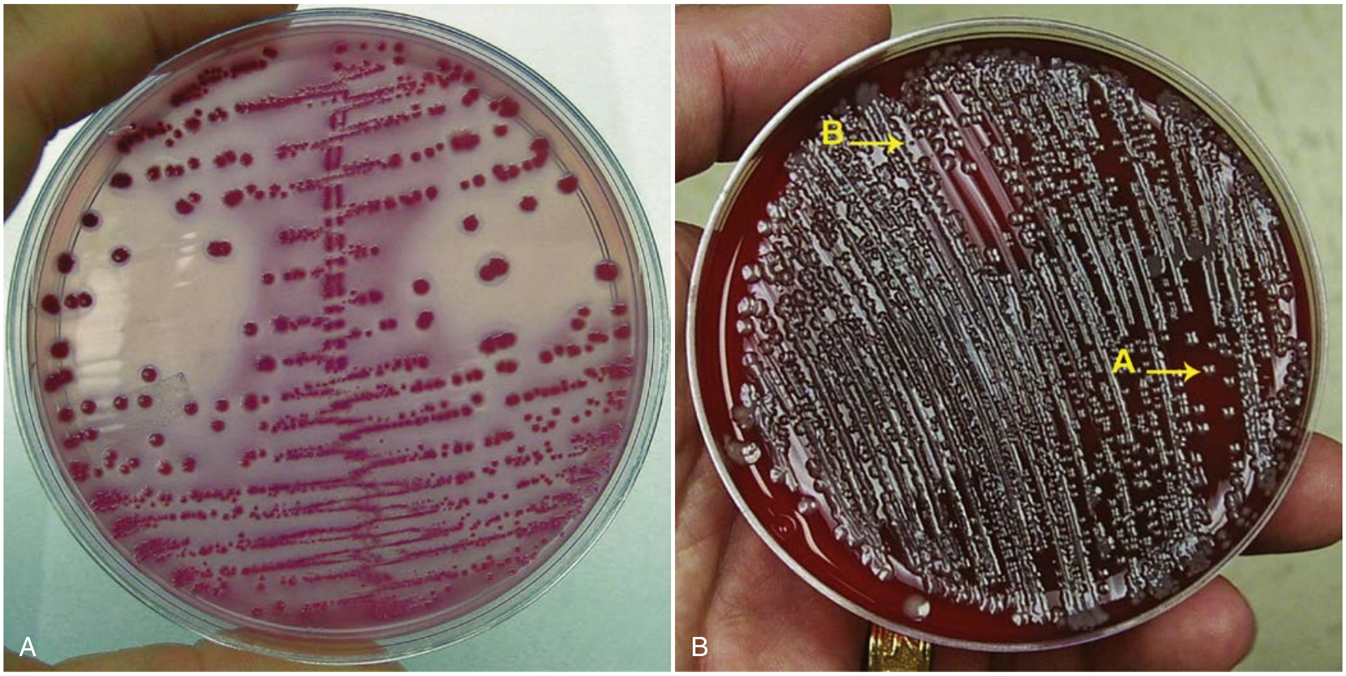
TABLE 72.2 Suggested Interpretative Guidelines for Urine Cultures

Result	Specific Specimen Type/Associated Clinical Condition, if Known	Workup
$\geq 10^4$ CFU/mL of a single potential pathogen or for each of two potential pathogens	CCMS urine/pyelonephritis, acute cystitis, asymptomatic bacteriuria, or catheterized urines	Complete[a]
$\geq 10^3$ CFU/mL of a single potential pathogen	CCMS urine/symptomatic male patients or catheterized urine or acute urethral syndrome	Complete
≥ Three organism types with no predominating organism	CCMS urine or catheterized urine	None; because of possible contamination, ask for another specimen
Either two or three organism types with predominant growth of one organism type and $<10^4$ CFU/mL of the other organism type(s)	CCMS urine	Complete workup for the predominating[b] organism(s); description of the organism(s)
$\geq 10^2$ CFU/mL of any number of organism types (set up with a 0.001- and 0.01-mL calibrated loop)	Suprapubic aspirates, any other surgically obtained urine (including ileal conduits, cystoscopy specimens)	Complete

[a] A complete workup includes identification of the organism and appropriate susceptibility testing.

CCMS, Clean-catch midstream urine; *CFU,* colony-forming unit.

[b] Predominant growth is 10^4 to 10^5 CFU/mL or more.



• Fig. 72.5 Culture results illustrating some of the various interpretative guidelines. (A) Growth of 10^5 CFU/mL or more of a lactose-fermenting gram-negative rod in a clean-catch midstream (CCMS) urine sample from a patient with pyelonephritis; complete workup would be done. (B) Growth of 10^5 CFU/mL or more of a lactose-fermenting gram-negative rod (*arrow A*) and less than 10^4 CFU/mL of another organism type (*arrow B*) from a CCMS urine; only the organism with a colony count of at least 10^4 to 10^5 CFU/mL would be worked up completely. *CFU*, Colony-forming units.

CASE STUDY 72.1

A 25-year-old female presented to her physician with severe suprapubic pain that increased during urination. Her physician diagnosed this as her fourth episode of bladder infection in the past year. He decided to order a urinalysis and a culture. The urinalysis was positive for leukocyte esterase, and the patient was treated with nitrofurantoin. The culture subsequently grew 10^3 staphylococci/mL.

Questions

1. Is this organism significant?
2. What manual testing procedure would you use to identify this species?
3. Is susceptibility testing indicated for this organism?
4. Would a rapid urine screen be helpful in diagnosing the infection in this young female?

PROCEDURE 72.1

Inoculating Urine With a Calibrated Loop

Purpose

Quantitate the number of organisms and amount of each present in a urine specimen to determine the clinical significance of growth and organisms present.

Principle

The number of microorganisms per milliliter recovered on urine culture can aid in the differential diagnosis of urinary tract infection (UTI). Plastic or wire loops, which are available commercially, have been calibrated to deliver a known volume of liquid when handled correctly, thus enabling the microbiologist to estimate numbers of organisms in the original specimen based on the colony-forming units (CFU) of growth on cultures.

Method

1. Flame a calibrated wire-inoculating loop and allow it to cool without touching any surface. Alternatively, aseptically remove a plastic calibrated loop from its package.
2. Mix the urine thoroughly and remove the top of the container. If the urine is in a small-diameter tube, the surface tension will alter the amount of specimen picked up by the loop. A quantitative pipette should be considered if the urine cannot be transferred to a larger container.
3. Insert the loop vertically into the urine (Fig. 72.2) to allow urine to adhere to the loop.
4. Spread the loopful of urine over the surface of the agar plate, as shown in Fig. 72.3. A standard quadrant streaking technique is also acceptable.
5. Without flaming, insert the loop vertically into the urine again for transfer of a loopful to a second plate. Repeat for each plate.
6. Incubate plates for at least 24 hours at 35°C to 37°C in air. Colonies are counted on each plate. The number of CFUs is multiplied by 1000 (if a 0.001-mL loop was used) or by 100 (if a 0.01-mL loop was used) to determine the number of microorganisms per milliliter in the original specimen.
7. Because antimicrobial treatment or other factors may inhibit initial growth, reincubate plates with no growth or tiny colonies for an additional 24 hours before discarding plates.
8. To store the inoculating loop, place (handle down) in a test tube taped to the wall, rather than flat on the bench, to prevent bending, which would destroy the calibration.

Interpretation and Results

	Midstream or Catheter Specimen	**Sterile Specimen (Suprapubic or Cystoscopy)**
One organism isolated[a] $\geq 10^4$ CFUs	Identification and sensitivity testing	Identification and sensitivity testing of any growth
Two organisms isolated $\geq 10^4$ CFUs	Identification and sensitivity testing of both organisms	Identification and sensitivity testing of any growth
Two organisms with one predominant isolate	Identification and sensitivity testing of the predominant organism	Identification and sensitivity testing of any growth
Three or more organisms present[a]	Mixed growth—report as probable contamination	Identification and sensitivity testing of any growth

[a] Correlate to patient's clinical presentation (signs and symptoms).

Note: Some exceptions requiring the identification and sensitivity on small quantities of a single isolate may include symptomatic patients on antimicrobial therapy, patients with chronic infections, or young children.

Chapter Review

1. Which of the following bacterial organisms is not considered a colonizer or normal microbiota of the urethra?
   - **a.** Diphtheroids (*Corynebacterium* spp.)
   - **b.** Lactobacilli
   - **c.** Anaerobic gram-negative bacilli
   - **d.** Aerobic gram-negative bacilli
2. Which of the following urine rapid screening tools test for the presence of PMNs by measuring the enzyme produced by PMNs?
   - **a.** Nitrate reductase test
   - **b.** Leukocyte esterase test
   - **c.** Catalase test
   - **d.** All the above
3. What term describes a bladder infection that is accompanied by physical symptoms of dysuria, frequency, and urgency?
   - **a.** Cystitis
   - **b.** Urethritis
   - **c.** Acute urethral syndrome
   - **d.** Pyelonephritis
4. Which of the following bacteria can hydrolyze urea via urease production, which results in an increase in urine pH that is toxic to kidney cells and stimulates the formation of kidney stones?
   - **a.** *E. coli*
   - **b.** *Proteus*
   - **c.** *S. aureus*
   - **d.** *P. aeruginosa*
5. Which of the following bacterial urine culture colony counts is highly indicative of infection in nonimmunocompromised patients with suspected urinary tract infections?
   - **a.** A colony bacterial count of $>10^5$ CFU/mL of urine
   - **b.** A colony bacterial count of $>10^4$ CFU/mL of urine
   - **c.** A colony bacterial count of $>10^2$ CFU/mL of urine
   - **d.** A colony bacterial count of $>10^3$ CFU/mL of urine
6. Which of the following tools have been used in the diagnosis of UTIs to discriminate among contamination, colonization, and infection?
   - **a.** Quantitative urine cultures
   - **b.** Qualitative urine cultures
   - **c.** Observation of cloudy, foul-smelling urine
   - **d.** Routine monitoring of nonsymptomatic patients
7. When setting up a urine culture, a calibrated loop is used that delivers a specific amount of urine to the media plate. What is that amount?
   - **a.** 0.01 or 0.001 mL of urine
   - **b.** 0.10 or 0.01 mL of urine
   - **c.** 0.001 or 0.0001 mL of urine
   - **d.** None of the above
8. **True or False**

_____ A pure culture of *S. aureus* is significant regardless of the number of CFUs.

_____ Screening for asymptomatic bacteriuria is recommended for nonpregnant females, diabetic females, older institutionalized subjects, patients with spinal cord injury, and catheterized patients.

_____ *S. aureus* adheres better to uroepithelial cells than *S. saprophyticus* or *S. epidermidis.*

_____ The hematogenous spread of urinary tract infections does not usually occur due to bacteremia.

_____ Urinary tract infections can lead to sepsis and are the most common health care–associated infection reported from hospitals and nursing homes in the United States.

_____ *Salmonella* spp. may be recovered from urine during the early stages of typhoid fever and should be reported immediately to the doctor.

_____ Factors that may decrease bacterial contamination of urine cultures are rapid transportation to the laboratory, refrigeration of urine in cases where there is testing delay, and having female patients cleanse the labia and collect a “midstream” specimen.

_____ Viruses are a common cause of urinary tract infection, and urine cultures that fail to grow on bacterial media should be inoculated into cell culture.

_____ Females more frequently develop UTIs by the ascending route of bacterial invasion because of the association with instrumentation (catheterization and cystoscopy).

_____ When collecting a urine specimen from patients with indwelling catheters, it is appropriate to obtain the specimen from the collection bag of the catheter.

_____ The calibrated loop used to inoculate urine cultures where lower numbers of organisms are suspected is the 0.001-mL volume loop.

9. Matching: *Match each term with the correct description.*

______ reflux
______ urethra
______ ureter
______ bacteriuria
______ Foley catheter
______ hematogenous
______ pyelonephritis
______ cystitis
______ urethritis
______ pyuria
______ systemic
______ GBS
______ UPEC

a. presence of bacteria in urine
b. affecting the body as a whole
c. group B streptococci
d. many leukocytes (white blood cells) in the urine
e. tube connecting the bladder and kidney
f. blood-borne
g. indwelling catheter
h. tube allowing urine to leave the bladder
i. infection of the kidney
j. uropathogenic *E. coli*
k. inflammation of the urethra
l. inflammation of the bladder
m. backward flow

10. Short Answer

(1) Explain the significance of the bacterial K-antigen.
(2) Name the single most important factor contributing to health care–associated urinary tract infections.
(3) What bacteria are normally involved in UTIs occurring by the hematogenous route?
(4) What anatomic feature of the urinary tract helps to prevent urinary tract infections?
(5) Define Tamm-Horsfall protein and defensins. How do these proteins aid in fighting off infection by uropathogens?
(6) Explain what the acronym “UPEC” stands for.
(7) What are pathogenicity islands?
(8) What might alert the microbiologist to an unusual cause of a urinary tract infection?

73

Genital Tract Infections

OBJECTIVES

1. Describe the basic anatomy of the male and female reproductive systems.
2. Define the following conditions: vaginitis, cervicitis, proctitis, bartholinitis, pelvic inflammatory disease (PID), epididymitis, prostatitis, orchitis, neoplasia, urethritis, and dysuria.
3. List microorganisms that commonly are associated with vaginitis, cervicitis, and PID.
4. Describe the normal microbiota of the male and female genital tracts, and differentiate normal flora from pathogenic organisms.
5. List the media used to selectively isolate and differentiate genital tract pathogens, including modified Thayer-Martin (MTM), New York City (NYC), and colistin nalidixic agar (CNA), and the organisms capable of growth on each.
6. Compare the recommended use of various collection swabs for genital tract specimens, including the organisms inhibited by each (cotton-tipped, with or without charcoal; calcium alginate; dacron; rayon).
7. Determine specimen acceptability based on collection, transport, and diagnostic test orders for a genital tract specimen.
8. Explain the significance of gram-negative intracellular diplococci in genital specimens from both men and women.
9. Correlate signs and systems of infections with the results of laboratory diagnostic procedures for identification of the etiologic agent associated with infections of the genital tract.

General Considerations

Anatomy

Familiarity with the anatomic structures is important for appropriate processing of specimens from genital tract sites and interpretation of microbiologic laboratory results. The key anatomic structures for the female and male genital tract in relation to other important structures are shown in Fig. 73.1.

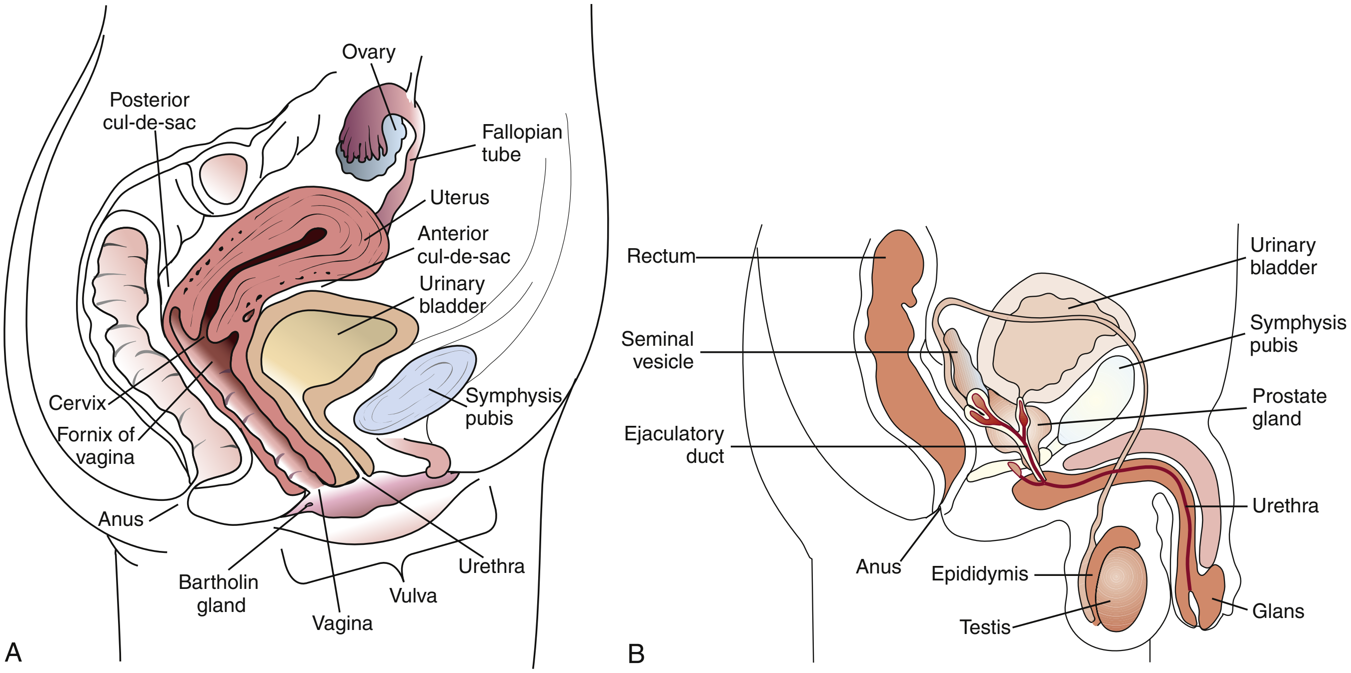
The female reproductive system consists of two main parts: the **uterus** and the **ovaries.** The uterus produces vaginal and uterine secretions and is the location where the human fetus grows and matures during reproduction. The ovaries connect to the uterus and the fallopian tubes. The ovaries produce the female eggs that pass through the fallopian tubes and will imbed in the uterus when fertilized by the male sperm. The uterus connects to the vaginal opening through the cervix.

The male reproductive system, unlike the female, consists of several organs that are located external to the abdominal cavity. The main organs consist of the **penis** and the **testes** that produce the semen and sperm for fertilization of the female egg. The sperm is stored in a small gland coiled around the testis, the **epididymis.** The **prostate gland** surrounds the ejaculatory duct and produces semen, prostatic fluid, and seminal fluid.

Resident Microbiota

The lining of the human genital tract consists of a mucosal layer of transitional (cells capable of undergoing shape change or transitions), columnar (ciliated and longer than wide), and squamous epithelial (thin and flat) cells. Various species of commensal bacteria colonize these surfaces, causing no harm to the host except under abnormal circumstances. The colonization of the surface by resident microbiota produces a biologic barrier preventing the adherence of pathogenic organisms. Normal urethral microbiota includes coagulase-negative staphylococci and corynebacteria, as well as various anaerobes. The **vulva** and penis, especially the area underneath the **prepuce** (foreskin) of the uncircumcised male, may harbor *Mycobacterium smegmatis* along with other gram-positive bacteria.

The microbiota of the female genital tract varies with the pH and estrogen concentration of the mucosa, which depend on the host's age. Prepubescent and postmenopausal females primarily harbor staphylococci and corynebacteria (the same microbiota present on surface epithelium); whereas females of reproductive age may harbor large numbers of facultative bacteria, such as Enterobacterales, streptococci, and staphylococci, as well as anaerobes, such as lactobacilli, anaerobic non–spore-forming bacilli and cocci, and clostridia. Lactobacilli are the predominant organisms in secretions in normal, healthy vaginas. The lactobacilli present in vaginal secretions metabolize glucose to lactic acid, resulting in a pH of approximately 4.0. The acidic pH coupled with the organism's ability to produce hydrogen peroxide prevents infection by exogenous sexually transmitted pathogens. Many women carry group B beta-hemolytic



• **Fig. 73.1** Location of key anatomic structures of the female (A) and male (B) genital tracts in relation to other major anatomic structures.

streptococci *(Streptococcus agalactiae),* which may be transmitted to the neonate. Although yeasts (acquired from the gastrointestinal tract) may be transiently recovered from the female vaginal tract, they are not considered normal microbiota.

Sexually Transmitted Diseases and Other Genital Tract Infections

Genital tract infections may be classified as endogenous or exogenous. Exogenous infections may be acquired as people engage in sexual activity, and these infections are referred to as **sexually transmitted diseases (STDs).** In contrast, endogenous infections result from normal genital microbiota.

Female genital tract infections can be divided into **lower genital tract** (vulva, vagina, and cervix) and **upper genital tract** (uterus, fallopian tubes, ovaries, and abdominal cavity) infections. Lower genital tract infections are commonly acquired by sexual or direct contact. Although the organisms that cause lower genital tract infections are not usually part of the normal genital tract microbiota, some organisms normally present in very low numbers can increase sufficiently to cause disease. Upper genital tract infections are frequently an extension of a lower tract infection in which organisms from the vagina or cervix travel into the uterine cavity and on through the endometrium to the fallopian tubes and ovaries. Similarly, an organism can spread along contiguous mucosal surfaces in the male from a lower genital tract site of infection (i.e., urethra) and cause infection in a reproductive organ, such as the epididymis.

Genital Tract Infections

Sexually Transmitted Diseases and Other Lower Genital Tract Infections

Lower genital tract infections may be acquired either through sexual contact with an infected partner or through nonsexual means. These infections are some of the most common infectious diseases.

Epidemiology and Etiologic Agents

STDs or sexually transmitted infections (STIs) are major public health problems in all populations and socioeconomic groups worldwide. The incidence and spread of STDs are greatly influenced by numerous factors, such as the availability of multiple sexual partners, the presence of asymptomatic infection, the frequent movement of people within populations, and increasing affluence.

The number of microorganisms that can cause genital tract infections is large. These organisms are diverse, representing all four major groups of microorganisms: bacteria, viruses, fungi, and parasites. The major causes of genital tract infections are listed in Table 73.1.

Routes of Transmission

Although genital tract infections can be caused by members of the patient's genital microbiota (endogenous infections), the overwhelming majority of lower genital tract infections are sexually transmitted.

Sexually Transmitted

Chlamydia trachomatis (CT), *Neisseria gonorrhoeae* (GC), *Trichomonas vaginalis,* human immunodeficiency virus

TABLE 73.1 Major Causes of Genital Tract Infections and Sexually Transmitted Diseases

Frequency	Disease	Agent	Organism Group
More Common	Genital and anal warts (condyloma); cervical dysplasia; cancer	Human papillomavirus	Viruses
	Vaginitis	*Gardnerella/Mobiluncus, Trichomonas vaginalis, Candida albicans*	Bacteria, parasites, fungi
	Urethritis/cervicitis (also acute salpingitis, acute perihepatitis, urethritis, pharyngitis)	*Neisseria gonorrhoeae, Chlamydia trachomatis, Ureaplasma urealyticum*	Bacteria
	Herpes genitalis (genital/skin ulcers)	Herpes simplex virus type 2 (less commonly type 1)	Viruses
	AIDS	Human immunodeficiency virus (HIV)	Viruses
	Hepatitis (acute and chronic infection)	Hepatitis B virus	Viruses
Less Common	Lymphogranuloma venereum	*C. trachomatis* (L-1, L-2, L-3 serovars)	Bacteria
	Granuloma inguinale	*Klebsiella granulomatis* (Donovania)	Bacteria
	Syphilis	*Treponema pallidum*	Bacteria
	Chancroid	*Haemophilus ducreyi*	Bacteria
	Scabies, mites	*Sarcoptes scabiei*	Ectoparasites
	Pediculosis pubis, “crabs” infestation	*Phthirus pubis*	Ectoparasites
	Enteritis (homosexuals/proctitis)	*Giardia duodenalis, Entamoeba histolytica, Shigella* spp., *Salmonella* spp., *Enterobius vermicularis, Campylobacter* spp., *Helicobacter* spp.	Bacteria, parasites
	Molluscum contagiosum	Poxlike virus	Viruses
	Heterophile-negative mononucleosis, congenital infections	Cytomegalovirus	Viruses

(HIV), *Treponema pallidum, Ureaplasma urealyticum, Mycoplasma hominis,* other mycoplasmas, herpes simplex virus (HSV), and others may be acquired during sexual activity. In addition, other agents that cause genital tract disease and may be sexually transmitted include adenovirus, hepatitis B, human T-cell lymphotropic virus (HTLV), coxsackie virus, molluscum contagiosum virus (a member of the poxvirus group), the human papillomaviruses (HPVs) of genital warts (condylomata acuminata; types 6, 11, and others) and those associated with cervical carcinoma (predominantly types 16 and 18, but numerous others are also implicated), *Klebsiella granulomatis,* and ectoparasites, such as scabies and lice. Some of these agents are not routinely isolated from clinical specimens. Infections with more than one agent may occur; therefore, dual or concurrent infections should always be considered.

An individual’s sexual habits and practices dictate potential sites of infection. Homosexual practices and increasingly common heterosexual practices of anal-genital or oral-genital intercourse allow for transmission of a genital tract infection to other body sites, such as the pharynx or anorectic region. In addition, these practices have required that other gastrointestinal and systemic pathogens also be considered etiologic agents of STDs. The intestinal protozoa *Giardia duodenalis, Entamoeba histolytica,* and *Cryptosporidium* spp. are significant causes of STDs, especially among homosexual populations. In the same group of patients, fecal pathogens, such as *Salmonella, Shigella, Campylobacter,* and *Microsporidium* are often transmitted sexually. Oral-genital practices may provide an opportunity for *N. meningitidis* to colonize and infect the genital tract. In fact, *N. meningitidis* is increasingly being recognized as a pathogen associated with urethritis. Outbreaks with *N. meningitidis* have been predominately identified in heterosexual males. Viruses shed in secretions or present in blood (cytomegalovirus [CMV]; hepatitis B, and possibly C and E; other non-A, non-B hepatitis viruses; HTLV type I [HTLV-I]; and HIV) are spread by sexual practices.

Certain infections that are sexually transmitted occur on the surface epithelium of or near the lower genital tract. The major pathogens of these types of infections include HSV, *Haemophilus ducreyi,* and *T. pallidum.*

Other Routes

Organisms may also be introduced into the genital tract by instrumentation, presence of a foreign body, or chemical or immunologic processes that cause irritation and can subsequently cause infection. These infections are often a result of infection with the same organisms capable of causing skin or wound infections. Infection can also be transmitted from mother to infant either *in vivo* or during delivery. For example, transplacental infection may occur with syphilis, HIV, CMV, or HSV. Infection in the newborn can also be acquired during delivery by direct contact with an infectious lesion or discharge in the mother and a susceptible mucous membrane, such as the eye in the infant. STDs such as HSV, *C. trachomatis,* and *N. gonorrhoeae* may be transmitted from mother to newborn in this manner. Other organisms, such as group B streptococci, *Escherichia coli,* and *Listeria monocytogenes* originating from the mother may also be transmitted to the infant before, during, or after birth. (Infections in the fetus and newborn are discussed later in this chapter.)

Clinical Manifestations

Clinical manifestations of lower genital tract infections are as varied and diverse as the etiologies.

Asymptomatic

Although symptoms of genital tract infections generally cause the patient to seek medical attention, a patient with an STD—especially a female—may be free of symptoms (i.e., asymptomatic). For example, gonorrhea *(N. gonorrhoeae)* or chlamydia *(C. trachomatis)* infection is usually obvious in males because of a urethral discharge, yet females with either or both infections may have either minimal symptoms or no symptoms at all. Also, the primary lesion of syphilis (chancre) can be unremarkable and go unnoticed by the patient. Therefore, the lack of symptoms does not guarantee the absence of disease. Unfortunately, these asymptomatic individuals can serve as reservoirs for infection and unknowingly spread the pathogen to other individuals. Asymptomatic infections in females caused by *N. gonorrhoeae* or *C. trachomatis* that go untreated can lead to serious sequelae, such as **pelvic inflammatory disease** (PID) or infertility.

Dysuria

Although a common presenting symptom associated with urinary tract infection, dysuria (painful urination) can also result from an STD caused by organisms such as *N. gonorrhoeae, C. trachomatis,* and HSV.

Urethral Discharge

The presence of an inflammatory exudate at the tip of the urethral meatus is generally observed in males; the symptoms of urethral infection in females are not commonly localized. Most males complain of discomfort at the penile tip as well as dysuria. Urethritis (swelling and irritation of the urethra) may be gonococcal, caused by *N. gonorrhoeae,* or nongonococcal. Nongonococcal urethritis (NGU) can be caused by common urinary tract infection isolates, adenoviruses, *C. trachomatis, T. vaginalis* (less frequently), and genital mycoplasmas, such as *M. hominis, Mycoplasma genitalium*, and *U. urealyticum.*

Lesions of the Skin and Mucous Membranes

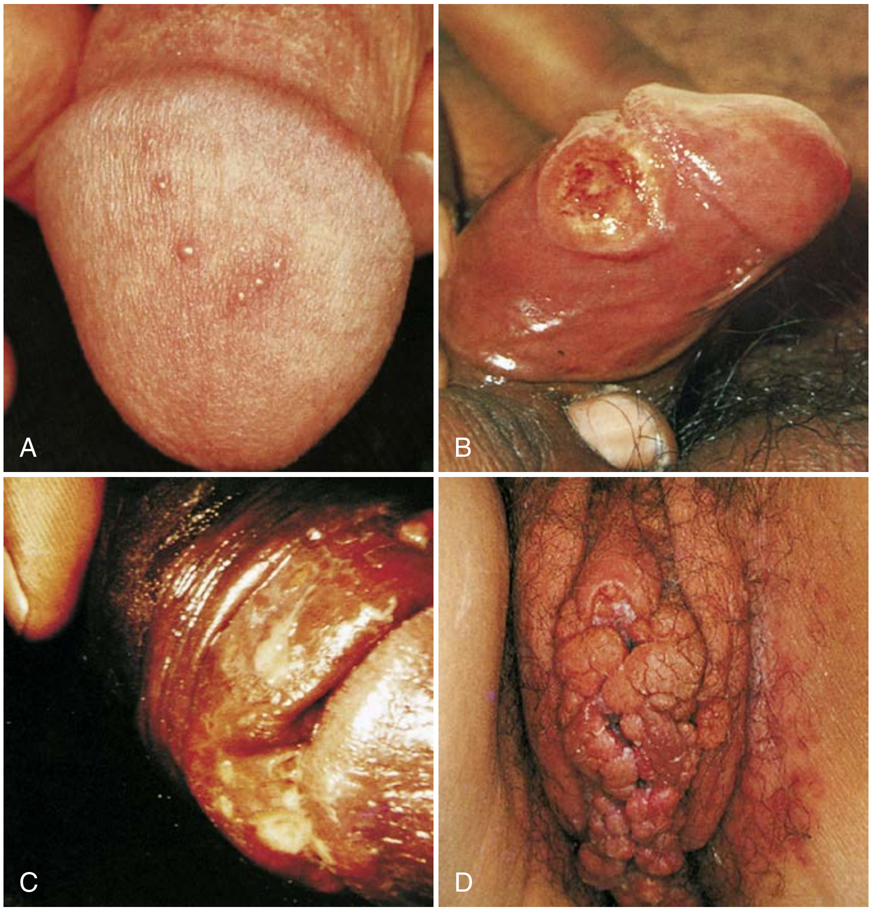
Numerous organisms can cause genital lesions that are diverse in both their appearance and their associated symptoms (Fig. 73.2) but are most often associated with STDs. The agents and their features of infection are summarized in Table 73.2. Some of these infections, such as genital herpes (caused by HSV) or genital warts (caused by HPVs and discussed in Chapter 65), are common; whereas others, such as lymphogranuloma venereum and granuloma inguinale, are uncommon in the United States. Genital skin and mucous membrane infections are often polymicrobial, making the diagnosis difficult. In addition, the characteristics of the lesions may vary from one type of infectious process to another for the same organisms. For example, specific HPV genotypes infect mucosal cells in the cervix and anus. The virus can cause a progressive spectrum of abnormalities classified as low-grade and high-grade **squamous intraepithelial neoplasia** (the process of rapid cell growth that is faster than normal and continues to grow—i.e., a tumor) and in some cases, progress to invasive cervical or anal cancer.

The patient's history of behavior and other relevant clinical information are important when attempting to identify the infectious agent associated with the lesion. For example, recurrent genital lesions and periods of **dysesthesias** (pain when touched) with intermittent outbreaks suggests infection with HSV 1 or 2. The virus remains inactive within the nerve ganglia during asymptomatic periods and then reemerges after an illness or other physiologic stress placed on the host. A patient's medication history may also attribute to the eruption of a genital lesion. An individual who has recently completed antibiotic therapy for an unrelated condition who has sexual contact with a partner infected with *Candida albicans* may be more susceptible to infection. In addition, patients who have underlying autoimmune diseases, such as Crohn disease or HIV infection, are more susceptible to other infections and the development of genital lesions.

Vaginitis

Inflammation of the vaginal mucosa, called **vaginitis,** is a common clinical syndrome accounting for approximately 10 million office visits each year. Females who present with vaginal symptoms often complain of an abnormal discharge and additional symptoms, such as an offensive odor or itching. **Vulvitis,** local irritation of external genitalia, may be associated with vaginitis. The three most common causes of vaginitis in premenopausal females are vaginal candidiasis, bacterial vaginosis (BV) (group B streptococci, *E. coli,* and enterococci), and trichomoniasis.

C. albicans causes about 80% to 90% of the cases of vaginal candidiasis; other species of *Candida* account for the remaining cases. Yeast can be carried vaginally in small



• **Fig. 73.2** Genital lesions of the skin and mucous membranes that are sexually transmitted. (A) Genital herpes showing vesicular lesions. (B) Typical chancre of primary syphilis. (C) Early chancroid lesion of the penis. (D) Condyloma acuminatum. (From Farrar WE, Wood MJ, Innes JA, et al. *Infectious Diseases Text and Color Atlas*. 2nd ed. London: Gower Medical Publishing; 1992.)

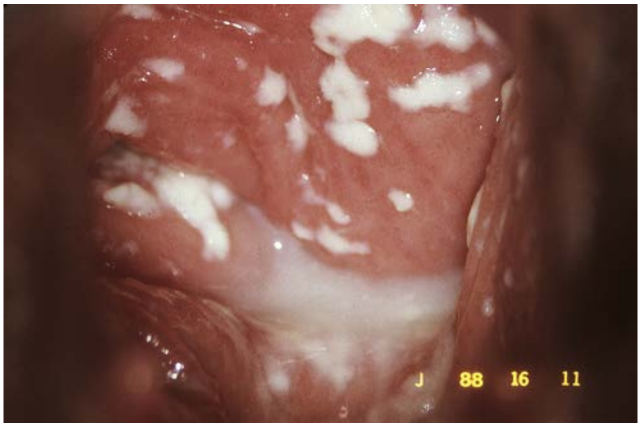
numbers and produce no symptoms. Most patients experiencing candidiasis complain of perivaginal itching, often with little or no discharge. Irritating symptoms such as erythema are also associated with candidiasis. Discharge is classically thick and "cheesy" in appearance (Fig. 73.3). Nonalbicans infections are more commonly associated with infections because of the increased use of topical antifungal genital creams and ointments.

Vaginal infection with *T. vaginalis,* a protozoan parasite, produces a profuse, slightly offensive, yellow-green discharge; patients commonly complain of itching. Additional symptoms may include dysuria and **dyspareunia** (persistent genital pain during intercourse). Some patients will present with a strawberry-appearing vaginal mucosa because of capillary dilation. The pH of the vaginal secretions will also typically increase to higher than 4.5, and numerous leukocytes and motile trophozoites may be present. About 25% of females carrying trichomonads are asymptomatic.

In addition to vaginitis caused by these two organisms, there is a third type referred to as **bacterial vaginosis** (BV). Initially, BV was thought to be associated with *Gardnerella vaginalis* infection, but *G. vaginalis* was isolated from 40% of women without vaginitis. Therefore, the presence of *G. vaginalis* should not be considered diagnostic for BV. BV is polymicrobial in etiology, involving *G. vaginalis* and other facultative and anaerobic organisms. The exact mechanism for the onset of BV is unknown, although it appears to be associated with a reduction in lactobacilli and hydrogen peroxide production, a rise in the vaginal pH, and the overgrowth of BV-associated organisms. Synergistic activity of various anaerobic organisms, including *Prevotella* spp., *Porphyromonas* spp., *Bacteroides* spp., *Peptostreptococcus* spp., *Mobiluncus* spp. (curved, motile rods), and *Mycoplasma* spp., as well as *G. vaginalis,* seems to contribute to the pathology of BV. BV is characterized by perivaginal irritation that is considerably milder than trichomoniasis or candidiasis and is usually associated with a foul-smelling discharge, often described as having a "fishy" odor. This odor is a result of products of bacterial metabolism (polyamines) being volatilized by vaginal fluids. Some patients also complain of abdominal discomfort. Dysuria and dyspareunia are rare. It appears that BV and trichomoniasis frequently coexist. Because BV can recur in the absence of sexual re-exposure and other settings (e.g., non–sexually active females or virgins), BV is not exclusively sexually transmitted. BV also increases a female's risk of acquiring HIV, is associated with

TABLE 73.2 Summary of Common Causes of Genital Lesions of the Skin and Mucous Membranes

Agent	Disease	Lesion	Major Associated Symptoms
Herpes simplex virus	Genital herpes	Papules, vesicles (blisters), pustules, or ulcers	Multiple lesions that are usually painful and tender, can recur (Fig. 73.2A).
Treponema pallidum	Primary syphilis	Genital ulcer (chancre)	Usually a single lesion, painless; lesion has even edges, represents the first of three stages of syphilis (Fig. 73.2B).
Haemophilus ducreyi	Chancroid	Papule that becomes pustular and ulcerates (chancroid); multiple ulcers may develop	Ulcer is deeply invasive, tender, painful, and purulent in appearance; edges of lesion are ragged (Fig. 73.2C).
Chlamydia trachomatis serotype L1, L2, and L3	Lymphogranuloma venereum	Small ulcer or vesicle that heals spontaneously without leaving a scar	After lesion heals, painful, swollen lymph nodes (lymphadenopathy) develop 2–6 weeks later; fever and chills; severe lymphatic obstruction and lymphedema can develop.
Klebsiella	Granuloma inguinale	Single or multiple subcutaneous nodules	Indolent and chronic course; nodules enlarge granulomatis and erode through the skin, producing a deep red, sharply defined ulcer that is painless.
Human papillomavirus	Condylomata acuminate (primary genotypes 6 and 11)	Genital warts	Warts have a cauliflower-like appearance; usually multiple lesions that can be flat or elevated; usually asymptomatic apart from physical presence (Fig. 73.2D).
	Condylomata planum (primary genotypes 16, 18, 31, 33)	Flat, genital warts	Cervical warts that must be visualized by using a magnifying lens after the application of acetic acid (called colposcopy); infections can cause neoplasias that, in some cases, can progress to cervical cancer.



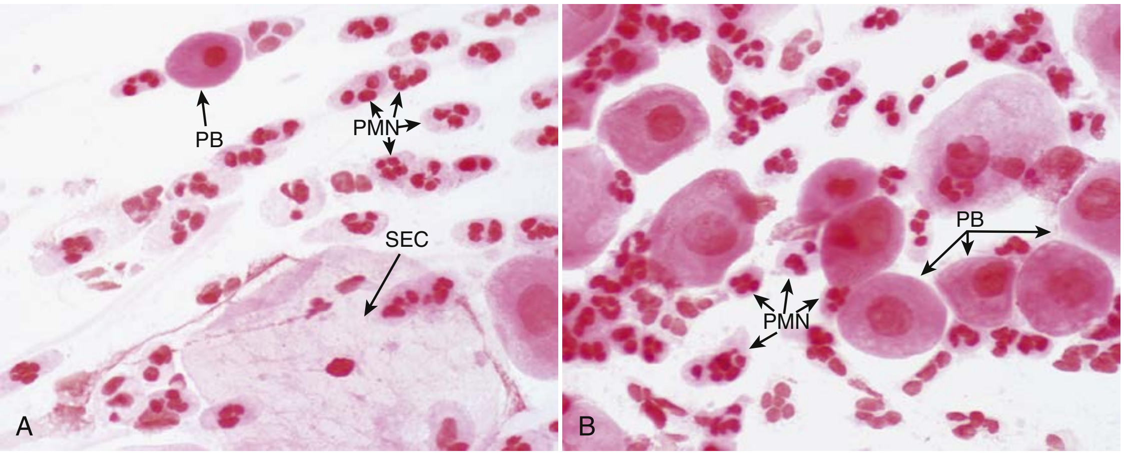
• **Fig. 73.3** Vulvovaginal candidiasis. Visible adherent white patches with surrounding erythema on the cervical mucosa.

increased complications in pregnancy, and may be involved in the pathogenesis of PID.

Although uncommon, there are other infectious causes of vaginitis. Three are briefly mentioned here because Gram stain of vaginal secretions may be helpful. The clinical syndrome referred to as **desquamate inflammatory vaginitis** resembles a bacterial vaginitis. The syndrome manifests in premenopausal patients with a diffuse, exudative vaginitis with massive vaginal cell exfoliation, purulent vaginal discharge, and an occasional vaginal and cervical spotted rash. Laboratory findings include an elevated pH (>5.0) of vaginal secretions. Also, numerous polymorphonuclear cells, an increased number of parabasal cells, the absence of gram-positive bacilli, and their replacement by occasional gram-positive cocci may be observed on direct Gram stain (Fig. 73.4). Basal cells appear because of the extensive exfoliation of epithelial cells. Symptoms associated with another disorder, lactobacillosis, resemble those of candidiasis and often follow antifungal therapy. Gram stain or wet mount typically reveals many very long lactobacilli. These predominately anaerobic lactobacilli are 40 to 75 µm in length and are significantly longer than the average normal microbiota lactobacillus (5 to 15 µm). Finally, preexisting lesions caused by other diseases may become secondarily infected with a mixed anaerobic microbiota of fusobacteria and spirochetes. This is referred to as **fusiform-spirochete disease;** this infection can progress rapidly. Gram stain examination reveals inflammatory cells in conjunction with gram-negative fusiform bacterial morphotypes and spirochetes.

Cervicitis

Polymorphonuclear neutrophils (PMNs) are normally present in the endocervix; however, an abnormally increased number of PMNs may be associated with **cervicitis** (inflammation of the cervix). Therefore, a purulent discharge from the endocervix can be observed in some cases of cervicitis. The endocervix is the site from which *N. gonorrhoeae* is



• **Fig. 73.4** Gram stain of vaginal secretions from a patient with desquamate inflammatory vaginitis. (A) Numerous polymorphonuclear cells *(PMNs),* a squamous epithelial cell *(SEC),* a parabasal cell *(PB),* and the absence of lactobacilli are observed. (B) Numerous PMNs, several PBs, and the absence of lactobacilli are observed.

most frequently isolated in females with gonococcal infections. In patients presenting with cervicitis, *C. trachomatis* and *M. genitalium* can also be isolated; chlamydia has not been associated with cervicitis. Patients are often infected with both *N. gonorrhoeae* and *C. trachomatis.* Because most females with cervicitis caused by gonococci or chlamydia are asymptomatic, and cervical abnormalities are either subtle or absent in these patients, an appropriate laboratory diagnosis to detect these organisms must be performed.

HSV and HPV can also infect the cervix. In females with herpes cervicitis, the cervix is friable (bleeds easily) and may have ulcers. Affected patients may also have lower abdominal pain.

Anorectal Lesions

As previously mentioned, because of the homosexual practice and increasingly common heterosexual practice of anal-genital intercourse, sites of infection in addition to those in the genital tract must be considered. The anorectum and pharynx are commonly infected with the classic STDs, including anal warts and cancer caused by HPV, as well as other viruses and parasites. Patients with symptoms of **proctitis** (inflammation of the rectum) caused by *N. gonorrhoeae* or *C. trachomatis* complain of itching, mucopurulent anal discharge, anal pain, bleeding, and **tenesmus** (painful straining during a bowel movement). Anorectal infection caused by HSV is associated with severe anal pain, rectal discharge, tenesmus, and systemic signs and symptoms, such as fever, chills, and headaches.

In HIV-infected individuals and other immunocompromised patients, these infections tend to last longer, are more severe, and are more difficult to treat compared with infection in immunocompetent individuals. Anorectal lesions are common in HIV-infected patients and include anal **condylomata**, anal abscesses, and ulcers. Anal abscesses and ulcers can be caused by various organisms, including CMV, *Mycobacterium avium* complex, HSV, *Campylobacter* spp., and *Shigella,* as well as traditional etiologic agents of STDs.

Bartholinitis

In adult females, the Bartholin gland is a 1-cm mucus-producing gland on each side of the vaginal orifice. Each gland has a 2-cm duct that opens on the inner surface of the labia minora. If infected, this duct can become blocked and result in a Bartholin gland abscess (**Bartholinitis**). Although *N. gonorrhoeae* and *C. trachomatis* can cause infection, anaerobic and polymicrobic infections originating from normal genital microbiota are more common.

Infections of the Reproductive Organs and Other Upper Genital Tract Infections

Besides the lower genital tract, infections can occur in the reproductive organs of both males and females.

Females

Infection of the female reproductive organs (i.e., uterus, fallopian tubes, ovaries, and even the abdominal cavity) can occur. The organisms spread as they ascend from lower tract sites of infection. Organisms may also be introduced to the reproductive organs by surgery, instrumentation, or during childbirth.

Pelvic Inflammatory Disease

PID is an infection that results when cervical microorganisms travel upward to the endometrium (inner membrane of the uterus), fallopian tubes, and other pelvic structures. This infection can produce one or more of the following inflammatory conditions: **endometritis, salpingitis** (inflammation of the fallopian tubes), localized or generalized peritonitis, or abscesses involving the fallopian tubes or ovaries. Patients with PID often have intermittent abdominal pain and tenderness, vaginal discharge, dysuria, and possibly systemic symptoms, such as fever, weight loss, and headache. Serious complications, such as permanent scarring of the fallopian tubes and infertility, can arise if PID is untreated.

TABLE 73.3 **Common Etiologic Agents of Prenatal and Neonatal Infections**

Time of Infection[a]	Route of Infection	Common Agents
Prenatal	Transplacental	Bacteria: *Listeria monocytogenes, Treponema pallidum, Borrelia burgdorferi* Viruses: cytomegalovirus (CMV), rubella, HIV, parvovirus B19, enteroviruses Parasites: *Toxoplasma gondii, Plasmodium* spp.
	Ascending	Bacteria: group B streptococci, *Escherichia coli, L. monocytogenes, Chlamydia trachomatis,* genital mycoplasmas Viruses: CMV, herpes simplex virus (HSV)
Natal	Passing through the birth canal	Bacteria: group B streptococci, *E. coli, L. monocytogenes, N. gonorrhoeae, C. trachomatis* Viruses: CMV, HSV, enteroviruses, hepatitis B virus, human immunodeficiency virus (HIV)
Postnatal	All the aforementioned routes, from the nursery environment, or from maternal contact (e.g., breastfeeding)	All agents listed previously and various organisms from the nursery environment, including gram-negative bacteria and viruses, such as respiratory syncytial virus

[a] Some newborns develop infections during the first 4 weeks of postnatal life. Infections may be delayed manifestations of earlier prenatal (before birth), natal, or postnatal (after birth) acquisition of pathogens.

Infection with *N. gonorrhoeae* or *C. trachomatis* in the lower genital tract can lead to PID if a female is not adequately treated. Other organisms, such as anaerobes, gram-negative rods, streptococci, and mycoplasmas, may ascend through the cervix, particularly after parturition (childbirth), dilation of the cervix, or abortion. The presence of an intrauterine device (IUD) is associated with a slightly higher rate of PID. Such infections caused by *Actinomyces* have been associated with the use of IUDs.

Infections After Gynecologic Surgery

After gynecologic surgery, such as a vaginal hysterectomy, patients frequently develop postoperative infections including pelvic cellulitis or abscesses. The major pathogens include normal human microbiota: aerobic gram-positive cocci, gram-negative bacilli, anaerobes such as *Peptostreptococcus* spp., and genital mycoplasmas.

Infections Associated With Pregnancy

Infections can also occur in females during pregnancy (prenatal) or after the birth (postpartum) of a child. These infections may, in turn, be transmitted to the infant; they are not only capable of compromising the mother's health but also the health of the developing fetus or neonate.

While developing within the uterus, the fetus is protected from most environmental factors, including infectious agents. The human immune system does not become fully competent until several months after birth. Immunoglobulins that cross the placental barrier, primarily immunoglobulin G (IgG), protect the newborn from many infections until the infant begins to produce immunoglobulins of his or her own in response to antigenic stimuli. This unique environmental niche, however, does expose the vulnerable fetus to pathogens present in the mother.

• BOX 73.1 **Organisms Commonly Isolated in Chorioamnionitis**

Anaerobic bacteria
Genital mycoplasmas
Group B streptococci
Escherichia coli

Prenatal infections (those that occur any time before birth) may be acquired hematogenously or by ascending genital tract routes from mother to infant. If the mother has a bloodstream infection, organisms can reach and cross the placenta, with possible spread of infection to the developing fetus. Organisms that can cross the placenta are listed in Table 73.3. Alternatively, organisms can also infect the fetus by the ascending route from the vagina through torn or ruptured fetal membranes. **Chorioamnionitis** is an infection of the uterus and its contents during pregnancy. This infection is commonly acquired when organisms spread from the vagina or cervix after premature or prolonged rupture of the membranes, or during labor. Organisms that are commonly isolated from amniotic fluid are listed in Box 73.1. Other maternal infections associated with adverse pregnancy outcomes that are not generally sexually transmitted include parvovirus B19, rubella, and *L. monocytogenes.*

Males

Infections in male reproductive organs can also occur and include epididymitis, prostatitis, and orchitis (testicular swelling). **Epididymitis,** an inflammation of the epididymis, is commonly seen in sexually active men. Patients complain of fever and pain and swelling of the testicle. Patients may also present with dysuria and a urethral discharge. There are two general types of epididymitis: nonspecific bacterial epididymitis caused by aerobic gram-negative rods, enterococci, or *Pseudomonas* spp.; and sexually transmitted epididymitis most commonly associated with *N. gonorrhoeae* and *C. trachomatis.* However, bacterial epididymitis is typically associated with an underlying genitourinary abnormality that requires surgery or urethral catheterization. Infections may also be caused by enteric bacteria and coagulase-negative staphylococci in males over 35 years of age and in homosexual males; these infections are often associated with obstruction by the prostate gland.

Prostatitis is a term to clinically describe adult male patients who have perineal, lower back, or lower abdominal pain, urinary discomfort, or ejaculatory complaints. Prostatitis is caused by both infectious and noninfectious means. Bacteria can cause an acute or chronic prostatitis. Patients with acute bacterial prostatitis have dysuria and urinary frequency—symptoms typically associated with lower urinary tract infection. These patients frequently have systemic signs of illness, such as fever. Chronic bacterial prostatitis is an important cause of persistent bacteriuria in males leading to recurrent bacterial urinary tract infections. The common causes of these infections are similar to the bacterial causes of lower urinary tract infections, such as *E. coli, Pseudomonas* spp., and other enteric organisms.

Finally, inflammation of the testicles, **orchitis,** is uncommon and generally acquired by the blood-borne dissemination of viruses. Mumps is associated with most cases. Patients exhibit testicular pain and swelling after infection. Infections range from mild to severe. In addition, **epididymo-orchitis** may occur after infection of the epididymis. Organisms typically isolated from bacterial orchitis include staphylococci, streptococci, *E. coli, Klebsiella pneumoniae,* and *Pseudomonas aeruginosa.*

Gonorrhea

Gonorrhea is a common STI caused by the bacterium *N. gonorrhoeae.* The infection may be spread by direct contact with secretions within the mouth, vagina, penis, or perianal region. The organism reproduces in warm, moist areas of the body including the urethra of males and females, fallopian tubes, uterus, and cervix.

Symptoms occur 2 to 5 days after infection in females. Males may not display symptoms for up to 1 month after infection. Symptoms in females include a vaginal discharge, pain and frequency on urination, sore throat, abdominal pain, fever, and painful sexual intercourse. Males experience pain and frequency during urination, a penile discharge, red or swollen urethra, and tenderness in the testes. The characteristics of the urethral discharge may vary from cloudy to clear and is therefore an unreliable indicator for gonococcal urethritis in males.

Gonorrhea can be directly diagnosed by Gram staining a sample of urethral discharge, cervical specimens, or joint fluids. *N. gonorrhoeae* is a gram-negative diplococcus with a characteristic kidney bean shape on Gram stain. The detection of intracellular diplococci in male secretions is diagnostic for *N. gonorrhoeae.* Extracellular diplococci in females is an indication of normal genital microbiota; however, intracellular diplococci indicate the presence of pathogenic organisms. Definitive diagnosis in females must include confirmation by culture. Infection with *N. gonorrhoeae* can lead to increased complications, including PID and gonorrheal ophthalmia neonatorum (eye infections) in newborns. *N. meningitidis* has been increasingly associated with urethritis.

Nongonococcal urethritis (NGU) is most commonly associated with *C. trachomatis* infection. Additional organisms that may be isolated from specimens in cases of NGU include *U. urealyticum* and *M. genitalium.*

Syphilis

Syphilis is an STD that is caused by the bacterium *T. pallidum.* The organism is transmitted from person to person through direct contact with infected lesions on the external genital area, vagina, anus, or rectum. Syphilis may also be transmitted from mother to baby during pregnancy.

Many individuals can be infected and remain asymptomatic for years, making the control of this disease difficult. The disease is characterized by three stages: primary, secondary, and tertiary (also referred to as late or latent syphilis). Direct diagnosis may be accomplished by dark-field microscopy of material from an infectious lesion. However, serology provides a more accurate and reliable method for diagnosis. (See Chapter 45 for a more detailed description of the disease and laboratory diagnosis.)

Laboratory Diagnosis of Genital Tract Infections

Lower Genital Tract Infections

Urethritis, Cervicitis, and Vaginitis

Specimen Collection

This discussion focuses on those specimens submitted for culture or direct examination. Procedures for the collection and transport of specimens for detection of agents by other noncultural methods (e.g., detection of infectious agents using nucleic acid–based tests) should be followed according to the respective manufacturer's instructions. (Refer to Table 5.1 for a review of collection, transport, and processing of genital tract specimens.)

Urethral. Urethral discharge may occur in both males and females infected with pathogens, such as *N. gonorrhoeae, N. meningitidis,* and *T. vaginalis.* The presence of infection is more likely to be asymptomatic in females, because the discharge is usually less profuse and may be masked by normal vaginal secretions. *U. urealyticum* can also be isolated from male urethral discharge.

A small urogenital swab designed expressly for collection of such specimens should be used. These swabs are made of cotton or rayon, treated with charcoal to adsorb material toxic to gonococci, and wrapped tightly over one end of a thin wire shaft. Cotton- or rayon-tipped swabs on a thin wire may also be used to collect specimens for isolation of mycoplasmas and chlamydiae. Calcium alginate swabs are generally more toxic for HSV, gonococci, chlamydia, and mycoplasmas than treated cotton swabs. Because dacron swabs are least toxic, they are recommended for viral specimens. Dacron-tipped swabs on plastic shafts are also acceptable for chlamydiae and genital mycoplasmas.

To obtain a urethral specimen, a swab is inserted approximately 2 cm into the urethra and rotated gently before withdrawing. Because chlamydiae are intracellular pathogens, it is important to remove epithelial cells (with the swab) from the urethral mucosa. Separate swabs for cultivation of gonococci, chlamydiae, and ureaplasma are required. When profuse urethral discharge is present, particularly in males, the discharge may be collected externally without inserting a sampling device into the urethra. However, a urethral swab for chlamydiae must be collected on males. A few drops of first-voided urine have also been used successfully to detect gonococci in males.

Because *T. vaginalis* may be present in urethral discharge, material for culture should be collected by swab, as described, and another specimen collected on a swab and placed into a tube containing 0.5 mL of sterile physiologic saline. This specimen should be delivered to the laboratory immediately. Direct wet mounts and cultures for *T. vaginalis* can be performed from this second specimen. Commercial media for culture of *Trichomonas* are available. The first few drops of voided urine make a suitable specimen for recovery of *Trichomonas* from infected males, if it is inoculated into culture media immediately. Alternatively, material may be smeared onto a slide for a fluorescent antibody stain. Plastic envelopes for direct examination and subsequent culture are also available (InPouch TV, BIOMED, White City, OR); sensitivity of this system is superior to other available methods, and organism viability is maintained up to 48 hours. In addition, several other techniques are available, including enzyme immunoassay, latex agglutination tests, and the Affirm VPIII probe (Becton Dickinson, Cockeysville, MD). Nucleic acid–based test methods are the most sensitive for the detection and identification of *T. vaginalis* directly in clinical specimens.

N. gonorrhoeae may be detected from clinical specimens using a variety of nucleic acid–based methods using a DNA probe that hybridizes to organismal ribosomal ribonucleic acid (rRNA). Fully automated systems for complete sample processing are available that reduce technical time. These tests are rapidly evolving and widely used for quick detection of *N. gonorrhoeae* from vaginal, urethral, thin-prep, and urine specimens. *N. meningitidis* should be considered when a urethral Gram stain indicates the presence of gram-negative intracellular diplococci and a nonculture based test, such as nucleic acid amplification test (NAAT), is negative for the presence of *N. gonorrhoeae.*

Cervical and Vaginal. Organisms that cause purulent vaginal discharge (vaginitis) include *T. vaginalis,* gonococci, *Candida* spp. and, rarely, beta-hemolytic streptococci. The same organisms that cause purulent infections in the urethra may also infect the epithelial cells in the cervical opening (os), as can HSV. Mucus is removed by gently rubbing the area with a cotton ball. The urethral swab is inserted into the cervical canal and rotated and moved from side to side for 30 seconds before removal.

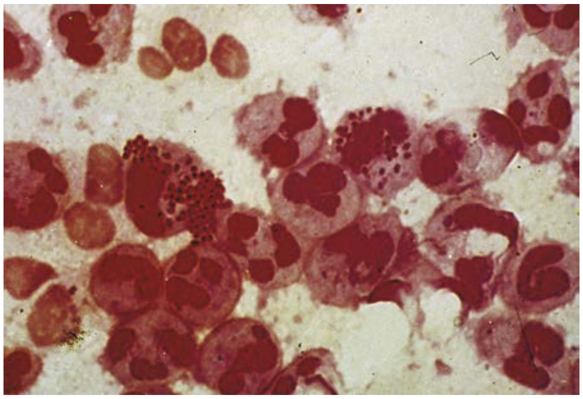
Swabs are handled as previously described for urethral swabs for isolation of *Trichomonas* and gonococci. Chlamydiae cause a mucopurulent cervicitis with discharge. Endocervical specimens are obtained after the cervix has been exposed with a speculum, which allows visualization of vaginal and cervical architecture, and after ectocervical mucus has been adequately removed. The speculum is moistened with warm water, because many lubricants contain antibacterial agents. Because normal vaginal secretions contain great quantities of bacteria, care must be taken to prevent or minimize contamination of swabs for culture by contact with these secretions. A small, nylon-bristled cytology brush, or Cytobrush, may be used to ensure that cellular material is collected. Collection may result in patient discomfort and bleeding.

In addition to cervical specimens, which are particularly useful for isolating herpes, gonococci, mycoplasmas, and chlamydiae, vaginal discharge specimens may be collected. Organisms likely to cause vaginal discharge include *Trichomonas,* yeast, and the agents of BV. Swabs for diagnosis of BV are dipped into the fluid that collects in the posterior fornix of the vagina.

Genital tract infections caused by sexually transmitted agents in children (preadolescents) are most often the result of sexual abuse. Because of medico-legal implications, the laboratory should treat specimens from such patients with extreme care, carefully identifying and documenting all isolates. Although nucleic acid–based testing methods are available for the identification of organisms associated with sexual abuse cases, culture remains the preferred method of detection for *C. trachomatis* and *N. gonorrhoeae* in medico-legal cases. In addition, cultivation of the isolate may be required to link the specific isolate to the perpetrator using epidemiologic studies. It is important to follow the current rules and regulations of each state for the collection and processing of isolates in these situations.

Because it is impossible to exclude contamination with vaginal microbiota, obtaining swabs of Bartholin gland exudate is not recommended. Infected Bartholin glands should be aspirated with needle and syringe after careful skin preparation, and cultures should be evaluated for anaerobes and aerobes.

Transport. Swabs collected for isolation of gonococci may be transported to the laboratory in modified Stuart's or Amie's charcoal transport media and held at room temperature until inoculated to culture media. Good recovery of gonococci is possible if swabs are cultured within 12 hours of collection. Material that must be held longer than 12 hours should be inoculated directly to one of the commercial systems designed for recovery of gonococci, described later in this chapter.

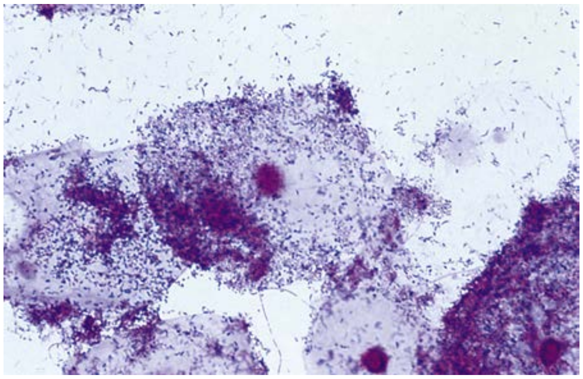


• **Fig. 73.5** Gram-negative intracellular diplococci, which are diagnostic for gonorrhea in urethral discharge and presumptive for gonorrhea in vaginal discharge.

Swabs for isolation of chlamydiae and mycoplasmas are transported in specific transport media containing antibiotics and other essential components. Specimens for chlamydia culture should be transported on ice. (Specimens transported at room temperature should be inoculated within 15 minutes of collection.) Specimens can be stored at 4°C for up to 24 hours. If culture inoculation will be delayed more than 24 hours, specimens should be quick-frozen in a dry ice and 95% ethanol bath and stored at −70°C until cultured. If collected and transported in specific transport media, specimens for genital mycoplasma culture may be transported on ice or at room temperature. If not in genital mycoplasma transport media, specimens should be transported on ice to suppress the growth of contaminating microbiota.

Direct Microscopic Examination

In addition to culture, urethral discharge may be examined by Gram stain for the presence of gram-negative intracellular diplococci (Fig. 73.5), usually indicative of gonorrhea in males. After inoculation to culture media, the swab is rolled over the surface of a glass slide, covering an area of at least 1 cm^2. Specimens collected from within the urethra may contain small cuboidal epithelial cells with a large nucleus. Numerous PMNs, more than four per oil immersion field, will also be visible in acute urethritis. If the Gram stain is characteristic of normal skin or genital microbiota, cultures of urethral discharge need not be performed. Urethral smears from females may also be examined. If extracellular organisms resembling *N. gonorrhoeae* are seen, the microbiologist should continue to examine the smear for intracellular diplococci. Presumptive diagnosis can be useful when decisions are to be made regarding immediate therapy, but confirmatory cultures or an alternative nonculture method should always be performed on specimens from females. Some strains of *N. gonorrhoeae* are sensitive to the amount of vancomycin present in selective media. If suspicious organisms seen on smear fail to grow in culture, reculture on chocolate agar without antibiotics may be warranted and *N. meningitidis* should also be considered. In addition, a Gram stain that contains numerous PMNs without intracellular gram-negative diplococci may also be suggestive of NGU.



• **Fig. 73.6** Clue cells in vaginal discharge suggestive of bacterial vaginosis.

Fluorescein-conjugated monoclonal antibody reagents are sensitive and specific for visualization of the inclusions of *C. trachomatis* in cell cultures or elementary bodies in urethral and cervical specimens containing cells. Reagents for direct staining of specimens are available commercially in complete collection and test systems, but the increased technologist time required limits the usefulness of this method for laboratories that receive many specimens, except as a confirmatory test for other antigen detection systems with borderline results. In some studies, the sensitivity of visual detection of chlamydia with these reagents has been similar to that of culture. False-positive results should not occur if at least 10 morphologically compatible fluorescing elementary bodies are seen on the smear. No direct visual methods exist for detection of mycoplasmas, but nucleic acid–based assays are the most sensitive for diagnosis of these fastidious organisms.

Direct microscopic examination of a wet preparation of vaginal discharge provides the simplest rapid diagnostic test for *T. vaginalis* and can be examined immediately. Motile trophozoites of *Trichomonas* can be visualized in a routine wet preparation in two thirds of cases or a direct fluorescent antibody (DFA) stain, Merifluor (chlamydia) (Meridian Diagnostics, Cincinnati, OH) may be used. Positive findings on a wet mount are diagnostic for trichomoniasis, but results are often negative in males.

Budding cells and pseudohyphae of yeast can also be easily identified in wet preparations by adding 10% potassium hydroxide (KOH) to a separate preparation, thereby dissolving host cell protein and enhancing the visibility of fungal elements.

BV, characterized by a foul-smelling discharge, can be diagnosed microscopically or clinically. The discharge is primarily sloughed epithelial cells, many of which are completely covered by tiny, gram-variable rods, and coccobacilli. These cells are called **clue cells** (Fig. 73.6). The absence of inflammatory cells in the vaginal discharge is another sign of BV. Although *G. vaginalis* has been historically associated with the syndrome and can be cultured on a human blood bilayer plate, culture is not recommended for diagnosis of BV. A clinical diagnosis of BV is dependent on the presence of three or more of the following criteria: homogeneous, gray discharge; clue cells seen on wet mount or Gram stain; a pH higher than 4.5; and an amine or fishy odor elicited by the addition of a drop of 10% KOH to the discharge on a slide or on the speculum.

BV may be differentiated from other vaginal infection by Gram stain (Fig. 73.7). A grading system for Gram stains of vaginal discharge has been developed (see Evolve Procedure 73.1). This system is based on the presence or absence of certain bacterial morphologies. Typically, in patients with BV, lactobacilli are either absent or few in number, whereas curved, gram-variable rods (*Mobiluncus* spp.) or *G. vaginalis* and *Bacteroides* morphotypes predominate. The Gram stain is more sensitive and specific than either the wet mount for detection of clue cells or culture for *G. vaginalis,* and the smear can be saved and reexamined later.

Culture

Samples for isolation of gonococci may be inoculated directly to culture media, obviating the need for transport medium. Commercially produced systems have been developed for this purpose, and many clinicians inoculate standard plates directly if convenient access to an incubator is available. Modified Thayer-Martin medium is most often used, although New York City (NYC) medium has the added advantage of supporting the growth of mycoplasmas and gonococci. The specimen swab is rolled across the agar with constant turning to expose all surfaces to the medium.

Specimens must be inoculated to additional media for isolation of yeast, streptococci, and mycoplasmas. Yeast grows well on Columbia agar base with 5% sheep blood and colistin and nalidixic acid (CNA), although more selective media are available. Most yeast and streptococci also grow on standard blood agar; thus, adding special fungal media, such as Sabouraud brain-heart infusion agar (SABHI), is unwarranted.

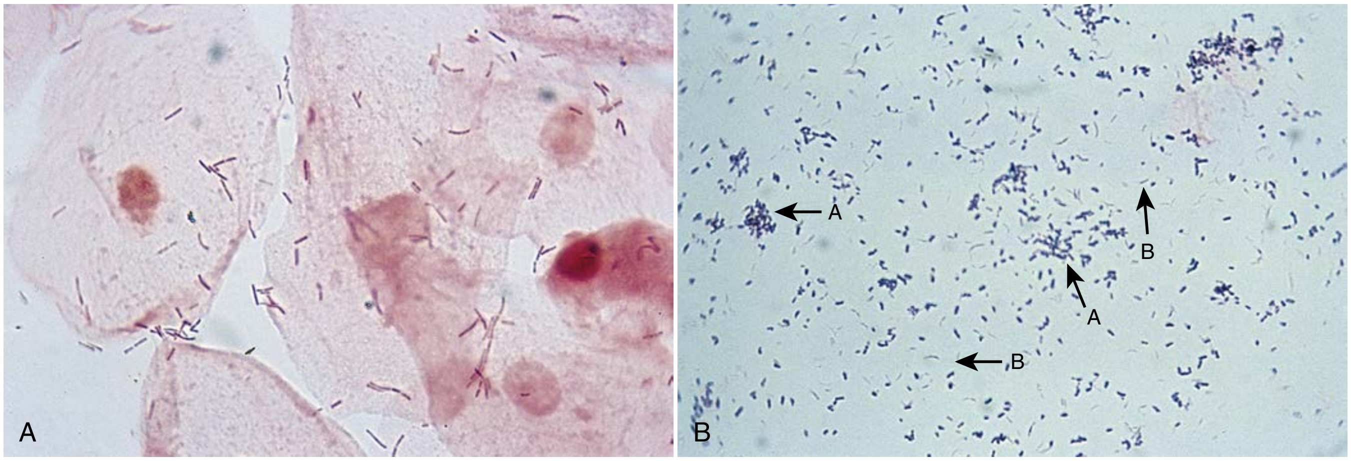
A specimen from the lower vagina followed by the rectum using the same swab at 35 to 37 weeks' gestation, reliably predicts the presence of group B streptococci at delivery. The swab should be transported to the laboratory in a nonnutritive transport medium, such as Amie's or Stuart's, without charcoal and then inoculated into a recommended selective broth medium, such as Todd-Hewitt broth supplemented either with gentamicin and nalidixic acid or with CNA referred to as LIM broth. Selective enrichment broths are subcultured to agar the next day to isolate and identify group B streptococci. In addition, the presence of group B streptococci in urine in any concentration from a pregnant female is a marker for heavy genital tract colonization. Any quantity of group B streptococci in urine from pregnant women should be worked up in the laboratory (Chapter 72).

T. vaginalis may be cultured in Diamond's medium (available commercially) or plastic envelopes inoculated with discharge material. Culture techniques are most sensitive. A commercially available biphasic genital mycoplasma culture system (Mycotrim-GU, Irvine Scientific, Santa Ana, CA) can be used to culture *Mycoplasma* spp. and *U. urealyticum,* although commercially prepared media are not as sensitive as fresh media. *M. genitalium* may not grow on commercial media because of the presence of thallium acetate.

Nonculture Methods

Various nonculture methods may be used to diagnose genital tract diseases, including serology, latex agglutination, nucleic acid hybridization and amplification assays, and enzyme immunoassays. Most assays detect a single or possibly two genital tract pathogens and are commercially available. These methods are described in more detail in chapters relating to individual pathogens.

As previously discussed, BV involves several organisms. Although the Gram stain offers high sensitivity and specificity, it is not immediately available. Currently, commercial laboratory tests are available to aid in the diagnosis of BV, but not all are available in the United States; a test for sialidase (OSOM BVBLUE, Sekisui Diagnostics, Framingham, MA) in conjunction with measuring pH has been reported to be



• **Fig. 73.7** (A) Predominance of lactobacilli in Gram stain from healthy vagina. (B) Absence of lactobacilli and presence of *Gardnerella vaginalis (A arrows)* and *Mobiluncus* spp. *(B arrows)* morphologies.

a rapid, highly sensitive, and specific means to diagnose BV. Sialidases are secreted from anaerobic gram-negative rods, such as *Bacteroides* and *Prevotella* as well as *Gardnerella,* and play a role in bacterial nutrition, cellular interactions, and immune response evasion, which in turn improves the ability of bacteria to adhere to, invade, and destroy mucosal tissue. A hybridization assay (Affirm VP III Microbial Identification Test; Becton Dickinson Microbiology Systems, Burlington, NC) is commercially available to diagnose BV, as well as genital tract infections caused by *Candida* spp. and *T. vaginalis.* Once the appropriate reagents and specimen are added to special trays, the entire hybridization assays are then performed using instrumentation (Fig. 73.8). Evaluations indicate this system is sensitive and specific.

In addition to microscopic examination, NAAT should be performed on vaginal, cervical, or urine specimens when cervicitis is suspected. A variety of assays are available for the detection of associated pathogens, such as the automated Aptima Combo 2 Assay (Fig. 73.9). This assay is a transcription-mediated amplification (TMA) test that utilizes target capture for the *in vitro* qualitative detection and differentiation of rRNA from *C. trachomatis* and/or *N. gonorrhoeae* using the Panther System (Hologic) as a testing platform.

Genital Skin and Mucous Membrane Lesions

External genital lesions are usually either vesicular or ulcerative. Causes of lesions can be determined by physical examination, histologic or cytologic examination, and microscopic examination or culture of exudate. Gram staining is typically not useful for the identification of organisms and the evaluation of genital lesions because of the presence of contaminating normal microbiota.

Vesicles in the genital area are almost always attributable to viruses, and herpes simplex is the most common cause. Epithelial cells from the base of a vesicle may be spread onto the surface of a slide (Tzanck smear) and examined for the typical multinucleated giant cells of HSV by staining with Wright-Giemsa stain or immunofluorescent antibody stains for viral antigens. NAATs are recommended for HSV testing that provide excellent sensitivity. Additionally, or alternatively, the material may be transported for culture of the virus as outlined in Evolve Procedure 73.2. Specimens positive for HSV will typically demonstrate cytopathic effect (changes in cell morphology) within 48 hours. Cultures have been largely replaced by NAATs.

Several commercial fluorescein-conjugated monoclonal and polyclonal antibodies directed against herpetic antigens of either type 1 or 2 are available. When fluorescent antibody–stained lesion material containing enough cells is viewed under ultraviolet light, the diagnosis can be made in 70% to 90% of patients. Laboratories that routinely process genital material for herpes should be using immunofluorescent staining reagents when a rapid answer is desired; otherwise, culture, which is generally positive in 2 days. Nonfluorescent markers, such as biotin-avidin-horseradish peroxidase or alkaline phosphatase, have also been conjugated to these specific antibodies, often allowing for earlier detection of herpes-infected cells in tissue culture monolayers.

Serologic assays are currently available to distinguish HSV 1 and HSV 2 and have been modified that allow the use of these tests in a clinic setting.

Lesions caused by HPV are typically characterized using the Papanicolaou smear (Pap) or a biopsy. These methods lack specificity, and, therefore, positive smears should be confirmed with a nucleic acid–based test such as hybrid capture or polymerase chain reaction.

Material from lesions suggestive of syphilis should be examined by dark-field or fluorescent microscopy. Dark-field microscopy is not useful for the differentiation of pathogenic from nonpathogenic treponemes. A two-step serologic test using the rapid plasma reagin (RPR), Venereal Disease Research Laboratory (VDRL), or unheated serum reagin (USR) test—followed by a confirmatory test—is the recommended procedure for the diagnosis of syphilis.

(Adapted from teaching materials, courtesy Jim Flanigan, American Society for Clinical Laboratory Science.)

(These procedures are described in Chapter 45.) NAAT have also been developed for the detection of *T. pallidum.*

All lesions suspected of infectious etiology may be Gram stained in addition to the procedures described. The smear of lesion material from a patient with chancroid may show many small, pleomorphic, slender, gram-negative rods and coccobacilli arranged in chains and groups referred to as a "school of fish," characteristics of *H. ducreyi.* However, culture has been shown to be more sensitive for diagnosis of this agent. Material collected on cotton or dacron swabs may be transported in modified Stuart's medium. Specimens should be inoculated to culture media within 1 hour of collection. A special agar, consisting of Mueller-Hinton–based chocolate agar enriched with 1% IsoVitaleX (Becton-Dickinson, Franklin Lakes, NJ) and vancomycin (3 mg/mL), has yielded good isolation if cultures are incubated in 5% to 7% carbon dioxide in a moist atmosphere, such as a candle jar. *H. ducreyi* grows best at 33°C. NAAT have also been developed for the detection of *H ducreyi.*

Granuloma inguinale *(K. granulomatis)* (Fig. 73.8) is diagnosed by staining a crushed preparation of a small piece of biopsy tissue obtained from the edge of the base of the ulcer with Wright's or Giemsa stain and finding characteristic **Donovan bodies** (bipolar staining rods within macrophages). No acceptable media for isolation of *K. granulomatis* are available.

Buboes

Buboes, swollen lymph glands in the inguinal (pelvic) region, are often evidence of a genital tract infection. Buboes are common in patients with primary syphilis, genital herpes, lymphogranuloma venereum, and chancroid. Patients with acquired immune deficiency syndrome (AIDS) may show generalized lymphadenopathy. Other diseases that are not sexually transmitted, such as plague, tularemia, and lymphoma, can also produce buboes. Material from buboes may be aspirated for microscopic examination and culture. Isolation by cell culture or the identification of *C. trachomatis* using nucleic acid–based test methods is considered diagnostic.

Infections of the Reproductive Organs

Pelvic Inflammatory Disease

PID is often caused by the same organisms that cause cervicitis or by organisms that make up the normal microbiota of the vaginal mucosa. Diagnosis is often made based on signs and symptoms. Because of the profuse normal microbiota of the vaginal tract, specimens must be collected in such a way as to prevent vaginal microbiota contamination. Aspirated material collected by needle and syringe represents the best specimen. If this cannot be obtained at the time of surgery or laparoscopy, collection of intrauterine contents using a protected suction curetting device or double-lumen sampling device inserted through the cervix is also acceptable. **Culdocentesis** (aspiration of fluid in the cul-de-sac), after decontamination of the vagina by povidone-iodine, is satisfactory but rarely practiced today.

Aspirated material should be placed into an anaerobic transport container. The presence of mixed anaerobic microbiota, gonococci, or both, can be rapidly detected from a Gram stain. Direct examination with fluorescent monoclonal antibody stain may also detect chlamydiae. All specimens should be inoculated to media that allow the recovery of anaerobic, facultative, and aerobic bacteria, gonococci, fungi, mycoplasmas, and chlamydiae. All material collected from normally sterile body sites in the genital tract should be inoculated to chocolate agar and placed into a suitable broth, such as thioglycollate, in addition to the other types of media noted. If only specimens obtained on routine swabs inserted through the cervix are available, cultures should be performed for detection of gonococci and chlamydiae.

Miscellaneous Infections

Infections of the male prostate, epididymis, and testes are usually bacterial. Uropathogens, such as *E. coli*, *P. aeruginosa*, and *Enterococcus* spp. cause more than 60% of acute bacterial prostatitis. In younger males, chlamydia and *N. gonorrhoeae* predominates as the cause of sexually transmitted epididymitis and possibly of prostatitis. Orchitis, or inflammation of the testes, can be caused by the same uropathogens as the other conditions as well as viral infections. The mumps virus is the cause of most cases of viral orchitis. Urine or discharge collected via the urethra is the specimen of choice unless an abscess is drained surgically or by needle and syringe. The first few milliliters of voided urine may be collected before and after prostatic massage to try to pinpoint the anatomic site of the infection. Cultures are inoculated to support the growth of anaerobic, facultative, and aerobic bacteria, as well as gonococci.

Infections of Neonates and Human Products of Conception

Suspected infections acquired by the fetus because of a maternal infection that crosses the placenta (congenital infection) can be diagnosed culturally or serologically in the newborn. Because maternal IgG crosses the placenta, serologic tests are often difficult to interpret (Chapter 9). Nucleic acid testing for viruses included in the *Herpesviridae* are more widely used and are more sensitive than cell culture and antigen detection. Although HSV, varicella-zoster virus (VZV), enteroviruses, and CMV can be cultured easily—as can most bacterial agents—rubella and parvovirus B19 are more difficult to culture. Nasal and urine specimens offer the greatest yield for viral isolation, although blood, cerebrospinal fluid, and material from a lesion can also be productive. Systemic neonatal herpes without lesions may be difficult to diagnose unless tissue biopsy material is examined, because the viruses may not be present in cerebrospinal fluid or blood. Bacteria and fungi can be isolated from lesions, blood, and other normally sterile sites.

Determining the presence of fetal immunoglobulin M (IgM) directed against the agent in question establishes the serologic diagnosis of congenital infection. Until recently, ultracentrifugation was required for separation of IgM from IgG, the only definitive means of preventing false-positive results caused by maternal IgG or fetal rheumatoid factor. Ion-exchange chromatography columns, antihuman IgG, and bacterial proteins that bind to IgG, are commercially available for removing cross-reactive IgG and rheumatoid factor to obtain more homogeneous IgM for differentiation of fetal antibody. Indirect fluorescent antibody and enzyme-linked immunosorbent assay (ELISA) test systems are commercially available to detect IgM against *T. gondii,* rubella, CMV, HSV, and VZV. Interference by rheumatoid factor is still a consideration in most commercial IgM test systems (Chapter 9). The ability to detect viral inclusions in tissue, conjunctiva scrapings, and vesicular lesions, traditionally performed with Giemsa stain, has been improved because of the availability of monoclonal and polyclonal fluorescent antibody reagents, which are described in the chapters that discuss individual agents.

Infections that infants can acquire as they pass through an infected birth canal or that are related to difficult labor, premature birth, premature rupture of the membranes, or other events include the following:

- HSV and CMV
- Gonorrhea
- Group B streptococcal sepsis
- Chlamydial conjunctivitis and pneumonia
- *E. coli* or other neonatal meningitis

In the laboratory, these infections are diagnosed by direct detection, including NAATS or culturing for the agents when possible, or by performing serologic tests. The appropriate specimens (e.g., cerebrospinal fluid, serum, pus, tracheal aspirate) should be examined and inoculated immediately. Routine body surface cultures of infants in intensive care have not been shown to be helpful for predicting subsequent disease. The use of viral cell culture methods has been replaced in most laboratories by NAAT methods.

Finally, certain infectious agents are known to cause fetal infection and even abortion. For example, *L. monocytogenes,* the causative agent of mild flulike symptoms in the mother, can cause extensive disease and abortion of the fetus if infection occurs late in the pregnancy. Therefore, isolation of the organism from the placenta and from tissues of the fetus is important.

PROCEDURE 73.1

Preparing and Scoring Vaginal Gram Stains for Bacterial Vaginosis

Organism Morphotype	Number/Oil Immersion Field	Score
Lactobacillus-like (parallel-sided, gram-positive rods)	>30	0
	5–30	1
	1–4	2
	<1	3
	0	4
Mobiluncus-like (curved, gram-negative rods)	>5	2
	<1–4	1
	0	0
Gardnerella/Bacteroides-like (tiny, gram-variable coccobacilli and rounded, pleomorphic, gram-negative rods with vacuoles)	>30	4
	5–30	3
	1–4	2
	<1	1
	0	0

Score	Interpretation
0–3	Normal
4–6	Intermediate; repeat test later
7–10	Bacterial vaginosis

Smear Preparation

1. Roll the swab of vaginal discharge over the surface of a slide.
2. Allow the smear to air dry, fix with methanol, and Gram stain.
3. Assign scores; refer to box above.
4. Add up total score and interpret as above.

From Nugent RP, Krohn MA, Hillier SL Reliability of diagnosing bacterial vaginosis is improved by a standardized method of Gram stain interpretation. *J Clin Microbiol*. 1991;29:297.

PROCEDURE 73.2

Collection of Material From Suspected Herpetic Lesions

Principle

Herpesvirus is best recovered from the base of active lesions in the vesicular stage. The older the lesion, the less likely it will yield viable virus.

Method

1. Open the vesicles with a small-gauge needle or Dacron-tipped swab.
2. Rub the base of the lesion vigorously with a small cotton-tipped or Dacron-tipped swab to recover infected cells.
3. Place the swab into viral transport medium and refrigerate until inoculated to culture media. Specimens in media may be stored at –70° C for extended periods without loss of viral yield.
4. If large vesicles are present, material for culture or nucleic acid testing may be aspirated directly by needle and syringe.
5. Material from another lesion can be applied directly to a glass slide for a Tzanck preparation (cytology), with Wright-Giemsa stain for detection of multinucleated giant cells or for fluorescent antibody stain for detection of viral antigens.

CASE STUDY 73.1

A 19-year-old female presented to the clinic with low-grade fever and abdominal pain of 2 days' duration. She had a vaginal discharge for the previous 4 days and was sexually active with multiple partners in the past 2 months. She used no contraceptives. Urine was collected for an amplified probe assay for *Chlamydia trachomatis* and for *Neisseria gonorrhoeae.* Routine genital culture of the cervix was also collected. She was given an injection of ceftriaxone and placed on doxycycline for 2 weeks.

Questions

1. DNA probe assays are routinely performed from urine specimens from teenagers, because they are easily obtained. Why did the physician also do a culture in this woman?
2. This woman likely has pelvic inflammatory disease (PID). If left untreated, many cases result in infertility. What are the causes of this infection?
3. In this case, the culture was positive for an oxidase-positive, gram-negative diplococcus. What is the likely agent?

Chapter Review

1. The following organisms are considered normal genital microbiota *except:*
  - **a.** Corynebacteria
  - **b.** *Staphylococcus epidermidis*
  - **c.** *G. vaginalis*
  - **d.** *Lactobacilli* spp.

2. Which of the following components constitute the upper genital tract of the female reproductive system?
  - **a.** Uterus, cervix, fallopian tubes, ovaries
  - **b.** Uterus, fallopian tubes, vagina, cervix, ovaries
  - **c.** Uterus, fallopian tubes, ovaries
  - **d.** Uterus, fallopian tubes, cervix, ovaries

3. Which organism is associated with sexually transmitted disease in homosexual populations?
  - **a.** *E. histolytica*
  - **b.** *Staphylococcus aureus*
  - **c.** HPV
  - **d.** *T. pallidum*

4. Transplacental transmission from mother to baby may be associated with:
  - **a.** *N. gonorrhoeae*
  - **b.** *C. trachomatis*
  - **c.** CMV
  - **d.** *C. albicans*

5. Although symptoms of genital tract infections generally cause the patient to seek medical attention, what is one of the problems associated with control of transmission of STDs?
  - **a.** Untreated infections can lead to serious underlying disease.
  - **b.** Lack of symptoms does not guarantee absence of disease.
  - **c.** Males are always aware of symptoms associated with STDs.
  - **d.** Females can be asymptomatic or symptomatic.

6. Rapid cell growth and the formation of a tumor may be associated with:
  - **a.** *N. gonorrhoeae*
  - **b.** *C. trachomatis*
  - **c.** *T. vaginalis*
  - **d.** HPV

7. Bacterial vaginosis is predominantly caused by:
  - **a.** *C. albicans*
  - **b.** *Trichomonas*
  - **c.** *G. vaginalis*
  - **d.** Polymicrobial vaginosis

8. The proper collection for the most isolates found in genital tract specimens recommends the use of:
  - **a.** Dacron swabs
  - **b.** Charcoal cotton or rayon swabs
  - **c.** Calcium alginate swabs
  - **d.** Rayon swabs

9. Gonococci recovery is improved when:
  - **a.** Stuart's medium is used for transport and refrigerated.
  - **b.** Samples are cultured within 12 hours of collection after refrigeration.
  - **c.** Special isolation media are used, and incubation conditions are commercially available.
  - **d.** No special processing is required for isolation from genital swabs.

10. True or False

_____ The identification of *Lactobacillus* spp. in significant numbers in a pregnant female is a sign of serious infection.

_____ The presence of increased numbers of polymorphonuclear cells in the endocervix is commonly associated with *N. gonorrhoeae* infection.

_____ Anaerobic and polymicrobic infections from normal genital microbiota are common in the formation of a Bartholin gland abscess.

_____ The presence of maternal IgG in the amniotic fluid is diagnostic of an infection *in utero*.

_____ Prostatitis is often associated with noninfectious etiologies.

11. Matching: *Match each term with the correct description.*

_____ CNA
_____ NYC
_____ epididymitis
_____ proctitis
_____ neoplasia
_____ dysuria
_____ urethritis
_____ vaginitis
_____ cervicitis
_____ bartholinitis
_____ PID
_____ MTM
_____ prostatitis
_____ orchitis

a. Bartholin gland
b. vaginal mucosa
c. urethra
d. mycoplasmas
e. coiled gland
f. cervix
g. painful urination
h. tumor
i. rectum
j. peritonitis
k. testes
l. *N. gonorrhoeae*
m. ejaculatory dysfunction
n. yeast

12. Short Answer

(1) Pelvic inflammatory disease is a result of infection when cervical microorganisms ascend upward in the female genital tract. Describe the diversity of symptoms and types of infections associated with PID.

(2) Infections can occur in women during pregnancy or after birth. What organism can cause infection in the fetus in either situation?

(3) Describe the relevance of the intracellular and extracellular presence of diplococci in both male and female patients.

74

Gastrointestinal Tract Infections

OBJECTIVES

1. Describe the general anatomy of the gastrointestinal tract and the relationship to transmission of infectious disease.
2. Differentiate normal human microbiota from pathogenic organisms and describe the relative numbers of organisms distributed throughout the gastrointestinal tract.
3. Identify nonbacterial agents of infection of the gastrointestinal tract and name their associated diseases.
4. Describe innate immunity as it relates to the gastrointestinal tract, including physical, chemical, and bacterial components.
5. Differentiate infections of the upper and lower gastrointestinal tract based on clinical manifestations including watery diarrhea and bloody diarrhea (dysentery).
6. Identify the major cause for antimicrobial therapy–associated diarrhea and the proper laboratory diagnostic procedure for identification, including the toxin assay.
7. Identify the most common causes for watery diarrhea, dysentery, pseudomembranous colitis, and infant botulism.
8. Describe the bacterial pathogenic mechanisms associated with gastrointestinal disease, including the presence and function of enterotoxins, attachment, and invasion mechanisms.
9. Determine the adequacy of a specimen based on collection, transport, and specimen type for the diagnosis of gastrointestinal infections.
10. Define the following media, including the organisms identified and the chemical properties associated with the selection and differentiation within the media: MAC, SMAC, EMB, HEK, XLD, SS, and Campy.
11. List the organisms and microbial products that can be detected by nonculture methods.
12. Explain how the use of culture independent methods affects the surveillance and trends in diagnostic testing and antimicrobial sensitivity patterns for epidemiological purposes.
13. Correlate patient signs and symptoms with laboratory results for the identification of the gastrointestinal pathogen.

Anatomy

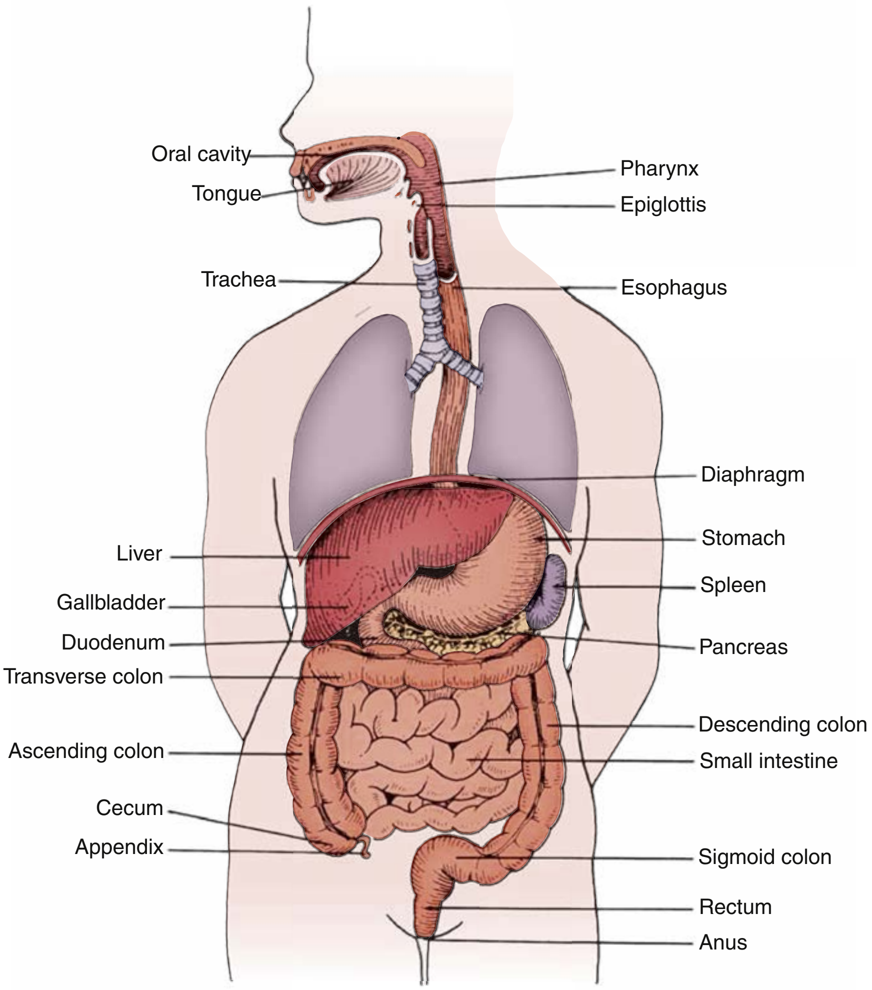
We are all connected to the external environment through our gastrointestinal (GI) tract (Fig. 74.1). What we swallow enters the GI tract and passes through the esophagus into the stomach, through the small and large intestines, and finally to the anus. During passage, fluids and other components are added to this material as secretory products of individual cells and as enzymatic secretions of glands and organs, and they are removed from this material by absorption through the gut epithelium.

The major components of the GI tract are listed in Box 74.1. The nature of the epithelial cells lining the GI tract varies with each portion. The lining of the GI tract is called the **mucosa.** Because of the differing nature of the mucosal surfaces of various segments of the bowel, specific infectious disease processes tend to occur in each segment.

The wall of the small intestine has folds that have millions of tiny, hairlike projections called **villi.** Each villus contains an arteriole, venule, and lymph vessel (Fig. 74.2). The function of villi is to absorb fluids and nutrients from the intestinal contents. Epithelial cells lining the surface of villi have a surface resembling a fine brush, referred to as a **brush border.** The brush border is formed by nearly 2000 microvilli per epithelial cell. Intestinal digestive enzymes are produced in brush border cells toward the top of the villi. Villi and microvilli help make the small intestine the primary site of digestion and absorption by significantly increasing the surface area; more than 90% of physiologic net fluid absorption occurs here. Mucus-secreting **goblet cells** are found in large numbers of villi and intestinal crypts.

Similar to the small intestine, the large intestine is composed of several segments (Box 74.1). The wall of the large intestine consists of **columnar epithelial cells,** many of which are mucus-producing goblet cells. In contrast to the small intestine, there are no villous projections into the lumen. The remaining excess fluid within the GI tract is resorbed through the cells lining the large intestine before waste is finally discharged through the rectum.

In addition to the previously discussed components of the GI tract, numerous other organs and structures are either located in the main digestive organs or open into them. These accessory organs and structures include the salivary glands, tongue, teeth, liver, gallbladder, and pancreas. Except for the teeth and salivary glands, these organs are illustrated in Fig. 74.1.



• **Fig. 74.1** General anatomy of the gastrointestinal tract. (From Broadwell DC, Jackson BS. *Principles of Ostomy Care*. St Louis: Mosby; 1982.)

Resident Gastrointestinal Microbiome

The GI tract contains vast, diverse normal microbiota. Although the acidity of the stomach prevents any significant colonization in a normal host under most circumstances, many species can survive passage through the stomach to become resident within the lower intestinal tract. Normally, the upper small intestine contains only sparse microbiota (bacteria, primarily streptococci; lactobacilli; and yeasts; 10^1 to 10^3/mL), but in the distal ileum, counts are about 10^6 to 10^7/mL, with Enterobacterales and *Bacteroides* spp. predominantly present.

The GI microbiome assists in the maintenance of a healthy environment and physiologic status of the host by providing essential vitamins and nutrients, influencing the natural and adaptive immune response as well as protecting the mucosal surface. An individual's GI microbiota varies according to the host genetics; nutritional status; previous or current antimicrobial, antifungal, or other chemotherapeutic agents; age; and the geographic region. Infants usually are colonized by normal human epithelial microbiota, such as staphylococci, *Corynebacterium* spp., and other gram-positive organisms (bifidobacteria, clostridia, lactobacilli, streptococci), within a few hours of birth. Over time, the content of the intestinal microbiota changes. The normal microbiota of the adult large bowel (colon) is established relatively early in life and consists predominantly of anaerobic species, including *Bacteroides, Clostridium, Peptostreptococcus, Bifidobacterium,* and *Eubacterium.* Aerobes, including *Escherichia* spp., other Enterobacterales, enterococci, and streptococci, are outnumbered by anaerobes 1000:1. The number of bacteria per gram of stool within the bowel lumen increases steadily as material approaches the sigmoid colon (the last segment). Eighty percent of the dry weight of feces from a healthy human consists of bacteria, which can be present in numbers as high as 10^{11} to 10^{12} colony-forming units (CFU)/g of stool.

All regions in the GI tract from the oral cavity to the anus contain three major bacterial phyla: *Bacteroidetes*, *Firmicutes*, and *Proteobacteria*. However, variations in the predominant

• BOX 74.1 Components of the Gastrointestinal Tract

Mouth
Oropharynx
Esophagus
Stomach
- *Fundus:* enlarged portion of the stomach to the left and above the opening of the esophagus into the stomach
- *Body:* central part of the stomach
- *Pylorus:* lower portion of the stomach

Small intestine
- *Duodenum:* uppermost division; attached to pyloric end of the stomach
- *Jejunum:* midsection of the small intestine
- *Ileum:* lower portion of the small intestine

Large intestine
- Cecum
- Colon
  Ascending colon: lies on the right side of the abdomen and extends up to the lower portion of the liver; the ileum joins the large intestine at the junction of the cecum and the ascending colon
  Transverse colon: passes horizontally across the abdomen
  Descending colon: lies on the left side of the abdomen in a vertical position
  Sigmoid colon: extends downward, subsequently joining the rectum
- Rectum
- Anal canal

phyla occur throughout the locations within the GI tract. The upper GI tract consists primarily of the bacterial families *Veillonellaceae, Pseudomonadaceae*, and *Streptococcaceae*, whereas the lower GI tract consists primarily of *Lachnospiraceae, Bacteroidaceae,* and *Ruminococcaceae.* There are differences in the reported populations of the normal microbiota that appear to be geographical in nature; more studies are needed as the details associated with a healthy normal GI tract microbiome is unraveled. This information may be useful for the development of appropriate measures in the prevention and treatment of autoimmune diseases, GI illness, and other disease syndromes through dietary intervention and the use of probiotics.

Gastroenteritis

Worldwide, diarrheal diseases are the ninth leading cause of death; about 48 million enteric infections occur each year. These infections cause significant morbidity and death, particularly in elderly people and children younger than 5 years of age. It has been estimated that nearly 1.7 billion cases of childhood diarrheal diseases, particularly in developing countries, occur globally each year. Even in developed countries, significant morbidity occurs as a result of diarrheal illness. Although acute diarrheal syndromes are usually self-limited, some patients with infectious diarrhea require diagnostic studies and treatment.

Pathogenesis

Similar to the pathogenesis of urinary tract infections, the host and the invading microorganism possess key features that determine whether an enteric pathogen is able to cause microbial diarrhea.

Host Factors

The human host has numerous defenses that normally prevent or control disease produced by enteric pathogens. For example, the acidity of the stomach effectively restricts the number and types of organisms that enter the lower GI tract. Normal peristalsis helps move organisms toward the rectum, interfering with their ability to adhere to the mucosa. The mucous layer coating the epithelium entraps microorganisms and helps propel them through the gut. The normal microbiota prevents colonization by potential pathogens.

Mucous membranes line the GI tract, as well as the respiratory and urogenital tracts. These membranes are exposed to the external environment in the form of food, water, and air. These membranes contain multiple cell types; some are secreting or absorbing cells that perform physiologic functions of the membrane, whereas others serve as protective barriers. For example, sets of specialized cells called **follicles** are part of the mucous membrane lining the GI tract and serve a protective function. Collections of follicles are called **Peyer patches.** Follicles contain M cells, macrophages, and B and T cells. As a result of the collective action of the follicle components after uptake and processing of the bacteria or antigens, secretory immunoglobulin A (sIgA) is released. Phagocytic cells and sIgA within the gut help destroy etiologic agents of disease, as do eosinophils, which are particularly active against parasites. Follicles and Peyer patches are found in the small and large intestines.

Other factors that determine the progression and potential invasion by pathogenic organisms include the host's personal hygiene and age. An initial step in the pathogenesis of enteric infections is ingestion of the pathogen. Most enteric pathogens, including bacteria, viruses, and parasites, are transmitted by the **fecal-oral route.** Enteric infections can be spread by contamination of food products or drinking water and then subsequent ingestion. The age of the host also plays a role in whether disease is established. For example, diarrheal infections caused by rotavirus or enteropathogenic *Escherichia coli* tend to affect young children.

Finally, the normal intestinal microbiome is an important factor in the host protection from the introduction of a potentially harmful microorganism. Whenever a reduction in normal microbiota occurs as a result of antibiotic treatment or some host factor, resistance to GI infection is significantly reduced. The most common example of the protective effect of normal microbiota is the development of the syndrome **pseudomembranous colitis (PMC).** This inflammatory disease of the large bowel is caused by the toxins of the anaerobic organism *Clostridioides difficile* and occasionally

other clostridia and perhaps even *Staphylococcus aureus.* The inflammatory disease seldom occurs except after antimicrobial or antimetabolite treatment that has altered the normal microbiota. Almost every antimicrobial agent and several cancer agents have been associated with the development of PMC. *C. difficile,* usually acquired from the hospital environment, is suppressed by normal microbiota. When the normal microbiota is reduced, *C. difficile* can multiply and produce its toxins. This syndrome is also known as **antibiotic-associated colitis (AAC).** Other microorganisms that may gain a foothold when released from selective pressure of normal microbiota include *Candida* spp., staphylococci, *Pseudomonas* spp., and various Enterobacterales.

Microbial Factors

The ability of an organism to cause GI infection depends not only on the susceptibility of the human host to the invading organism but also on the organism's virulence traits. To cause GI infection, a microorganism must possess one or more factors that allow it to overcome host defenses or it must enter the host at a time when one or more of the innate defense systems are inactive. For example, certain stool pathogens are able to survive gastric acidity only if the acidity has been reduced by bicarbonate, other buffers, or by medications for ulcers (e.g., cimetidine, ranitidine, H_2 blockers). Pathogens ingested with milk have a better chance of survival because milk neutralizes stomach acidity. Organisms such as *Mycobacterium tuberculosis, Shigella, E. coli* O157:H7, and *C. difficile* (a spore-forming bacterium) can withstand exposure to gastric acids and thus require much smaller infectious doses than do acid-sensitive organisms such as *Salmonella.*

Primary Pathogenic Mechanisms

Because the normal adult GI tract receives up to 8 L of ingested fluid daily, plus the secretions of the various glands that contribute to digestion (salivary glands, pancreas, gallbladder, stomach), of which all but a small amount must be resorbed, any disruption of the normal flow or reabsorption of fluid will profoundly affect the host. Depending on how they interact with the human host, enteric pathogens may cause disease in one or more of the following three ways:

- Changing the delicate balance of water and electrolytes in the small bowel, resulting in massive fluid secretion. In many cases, this process is mediated by enterotoxin production. This is a noninflammatory process.

TABLE 74.1 Examples of Microorganisms That Cause Gastrointestinal Infection for Each Primary Pathogenic Mechanism

Mechanism	Examples of Microorganisms
Toxin Production	
Enterotoxin	*Vibrio cholera* Noncholera vibrios *Shigella dysenteriae* type 1 Enterotoxigenic *Escherichia coli* *Salmonella* spp. *Clostridioides difficile* (toxin A) *Aeromonas* *Campylobacter jejuni* subsp. *jejuni*
Cytotoxin	*Shigella* spp. *C. difficile* (toxin B) *Entamoeba histolytica* Enterohemorrhagic *Escherichia coli*
Neurotoxin	*Clostridium botulinum* *Clostridium perfringens* *Staphylococcus aureus* *Bacillus cereus*
Attachment within or close to mucosal cells/adherence	Enteropathogenic *E. coli* Enterohemorrhagic *E. coli* *Cryptosporidium parvum* *Cystoisospora belli* Rotavirus Hepatitis A, B, C Noroviruses
Invasion	*Shigella* spp. Enteroinvasive *E. coli* *Entamoeba histolytica* *Neobalantidium coli* *C. jejuni* subsp. *jejuni* *Plesiomonas shigelloides* *Yersinia enterocolitica* *Edwardsiella tarda*

- Causing cell destruction or a marked inflammatory response after invasion of host cells and possible cytotoxin production, usually in the colon.
- Penetrating the intestinal mucosa, with subsequent spread and multiplication in lymphatic or reticuloendothelial cells outside of the bowel; these infections are considered systemic infections.

Examples of microorganisms for each of these pathogenic mechanisms are listed in Table 74.1.

Toxins

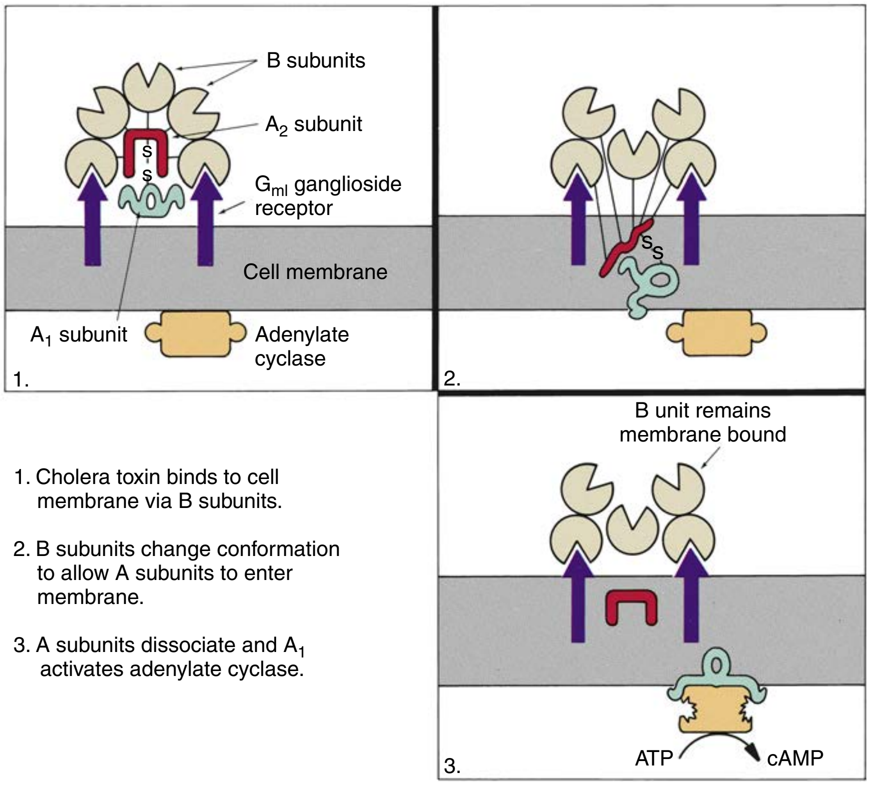
Enterotoxins. **Enterotoxins** alter the metabolic activity of intestinal epithelial cells, resulting in an outpouring of electrolytes and fluid into the lumen. They act primarily in the jejunum and upper ileum, where most fluid transport takes place. The stool of patients with enterotoxic diarrheal disease involving the small bowel is profuse and watery, and blood or polymorphonuclear neutrophils are not prominent features.

The classic example of an enterotoxin is that of *Vibrio cholerae* (Fig. 74.3). This toxin consists of two subunits, A and B. The A subunit is composed of one molecule of A_1, the toxic moiety, and one molecule of A_2, which binds an A_1 subunit to five B subunits. The B subunits bind the toxin to a receptor (a ganglioside, an acidic glycolipid) on the intestinal cell membrane. Once bound, the toxin acts on adenylate cyclase enzyme, which catalyzes the transformation of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). Increased levels of cAMP stimulate the cell to actively secrete ions into the intestinal lumen. To maintain osmotic stabilization, the cells then secrete fluid into the lumen. The fluid is drawn from the intravascular fluid store of the body. Patients therefore can become dehydrated and hypotensive rapidly. *V. cholerae* inhabits sea and stagnant water and is spread in contaminated water. The organisms have been isolated from coastal waters of several states, and sporadic cases of cholera occur in the United States. Additional information about *V. cholerae* is provided in Chapter 25.

Other organisms also produce a cholera-like enterotoxin. A group of vibrios similar to *V. cholerae* but serologically different, known as the noncholera vibrios, produce disease clinically identical to cholera, affected by a very similar toxin. The heat-labile toxin (LT) elaborated by certain strains of *E. coli,* called enterotoxigenic *E. coli* (ETEC), is similar to cholera toxin, sharing cross-reactive antigenic determinants. The enterotoxins of some *Salmonella* spp. (including *Salmonella enterica* subsp. *arizonae*), *Vibrio parahaemolyticus,* the *Campylobacter jejuni* subsp. *jejuni, C. jejuni* subsp. *doylei, Clostridium perfringens, C. difficile, Bacillus cereus, Aeromonas, Shigella dysenteriae,* and many others also cause positive reactions in at least one of the tests for enterotoxin (discussed later). The exact contribution of these enterotoxins to the pathogenicity of most stool pathogens remains to be elucidated.

Certain strains of *E. coli,* in addition to producing an LT similar to cholera toxin, also produce a heat-stable toxin (ST) with other properties. Although ST also promotes fluid secretion into the intestinal lumen, its effect is mediated by activation of guanylate cyclase, resulting in increased levels of cyclic guanylate monophosphate (GMP), which yields the same net effect as increased cAMP. Tests for ST include commercial immunoassays for the detection of Shiga toxin or serotyping for the O157 lipopolysaccharide. There are several Food and Drug Administration (FDA)-approved assays for the detection and diagnosis of STEC, *Salmonella,* and *Shigella*/EIEC (Chapter 19). In addition, there are chromogenic agars for the visual detection of O157:H7 after direct inoculation as a primary culture medium.

Cytotoxins. **Cytotoxins,** which constitute the second category of toxins, disrupt the structure of individual intestinal epithelial cells. When destroyed, these cells slough from the surface of the mucosa, leaving it raw and unprotected. The secretory or absorptive activities of the cells no longer function properly. The damaged tissue evokes a strong inflammatory response from the host, further inflicting



1. Cholera toxin binds to cell membrane via B subunits.

2. B subunits change conformation to allow A subunits to enter membrane.

3. A subunits dissociate and A_1 activates adenylate cyclase.

• **Fig. 74.3** The structure and action of cholera toxin.

tissue damage. Numerous polymorphonuclear neutrophils and blood are often seen in the stool, and pain, cramps, and tenesmus (painful straining during a bowel movement) are common symptoms. The term **dysentery** refers to this destructive disease of the mucosa, almost exclusively occurring in the colon. Cytotoxin has not yet been shown to be the sole virulence factor for any etiologic agent of GI disease, because most agents produce a cytotoxin in conjunction with other factors.

E. coli strains seem to possess virulence mechanisms of many types. Some strains produce a cytotoxin capable of destroying epithelial cells and blood cells. Certain strains produce a cytotoxin that affects Vero cells (African green monkey kidney cells) and resemble the cytotoxin produced by *S. dysenteriae* (Shiga toxin); such strains of *E. coli* are associated with hemorrhagic colitis and after infection result in sequelae such as hemolytic-uremic syndrome (HUS) and thrombotic thrombocytopenia purpura (TTP). These strains of *E. coli* are referred to as enterohemorrhagic *E. coli,* also referred to as serotoxigenic. See Chapter 19 for more information related to toxigenic *E. coli.* Table 74.2 summarizes the key pathogenic features of the primary groups of diarrheagenic *E. coli.*

C. difficile produces a cytotoxin, the presence of which is a most useful marker for diagnosis of PMC. *S. dysenteriae, S. aureus, C. perfringens,* and *V. parahaemolyticus* produce cytotoxins that contribute to the pathogenesis of diarrhea, although they may not be essential for the initiation of disease. Other vibrios, *Aeromonas hydrophila, Entamoeba histolytica,* and *C. jejuni* subsp. *jejuni,* the most common cause of GI disease in many areas of the United States, have been shown to produce cytotoxins.

C. difficile toxigenic strains produce two protein exotoxins, referred to as toxin A and toxin B. Both toxins bind to receptors on the brush border of the intestinal epithelium and are then internalized. Once inside the cell, both toxins modify proteins that are involved in the regulation of the actin cytoskeleton. This affects actin polymerization, causing disturbances and separation of the cell-to-cell tight junctions, rupturing the cells and causing mucosal damage.

S. dysenteriae produces a very potent cytotoxin referred to as type 1. This toxin is also produced by various strains of *E. coli* (STEC). The cytotoxin is an A_1-B_5 protein toxin. The toxin targets the GB3 (globotriaosylceramide) membrane receptor; the toxin becomes internalized and is transported into the endoplasmic reticulum (ER) and to the nuclear membrane. The A subunit of the toxin is then able to cleave the 28S ribosomal ribonucleic acid (rRNA) interfering with protein synthesis that results in host cell death. The ultimate effect is vascular damage to the endothelial surface, bloody diarrhea, and potentially HUS.

Bacteria are not the only toxin-producing organisms capable of causing cellular pathology within the GI tract. *E. histolytica* produces a phospholipase A and pore-forming peptides that upon direct contact with phagocytic cells result in direct cell death, reducing effective clearing of the protozoan parasite.

Neurotoxins. Food poisoning, or **intoxication,** may occur as a result of ingesting toxins produced by microorganisms. The microorganisms usually produce their toxins

TABLE 74.2 **Overview of the Primary Groups of *Escherichia coli* That Cause Diarrhea in Humans**

Type	Primary Mode of Pathogenesis	Other Comments
Enterotoxigenic (ETEC)	Produces heat-labile (LT) or heat-stable (ST) enterotoxins; genes of both toxins reside on a plasmid; LTs are closely related in structure and function to cholera toxin; STs result in net intestinal fluid secretion by stimulating guanylate cyclase.	Common cause of traveler's diarrhea; infects all ages.
Enteroaggregative (EAEC)	Binds to small intestine cells via fimbriae encoded by a large molecular weight plasmid, forming small clumps of bacteria on the cell surface; other plasmid-borne virulence factors include structured pilin, a heat-stable enterotoxin, novel antiaggregative protein, and a heat-labile enterotoxin, all believed to be the cause of the associated diarrhea.	Infects primarily young children.
Enteroinvasive (EIEC)	Pathogenesis has yet to be totally elucidated; studies suggest that mechanisms by which diarrhea results are virtually identical to those of *Shigella* spp.	Very difficult to distinguish from *Shigella* spp. and other *E. coli* strains.
Enteropathogenic (EPEC)	Initially attaches in the colon and small intestine and then becomes intimately adhered to intestinal epithelial cells, subsequently causing the loss of enterocyte microvilli (effacement); genes for attachment/effacement reside in a cluster on the bacterial chromosome (i.e., pathogenicity island).	Diarrhea in infants, particularly in large urban hospitals.
Enterohemorrhagic (STEC)	Attaches to and effaces gut epithelial cells in a similar manner as EPEC; in addition, STEC elaborates Shiga toxins.	Although many outbreaks are caused by *E. coli* O157:H7, other serotypes have been implicated in outbreaks and sporadic cases. Gene recombination among strains makes classification difficult.
	Produce one or more Shiga toxins referred to as verocytotoxins. Attaches to and effaces gut epithelial cells in a similar manner as EPEC.	0157 STEC serotypes; contains most common serotypes 0157:H7 and nonmotile 0157: NM. There are more than 150 non-0157 serotypes that have been isolated from patients with diarrhea or hemolytic-uremic syndrome.

in foodstuffs before they are ingested; thus, the patient ingests preformed toxin. Strictly speaking, these syndromes are not GI infections but rather intoxications; because they are acquired by ingestion of microorganisms or their products, they are considered in this chapter. Particularly in staphylococcal food poisoning and botulism, the causative organisms may not be present in the patient's bowel (Box 74.2).

Bacterial agents of food poisoning that produce neurotoxins include *S. aureus* and *B. cereus.* Toxins produced by these organisms cause vomiting, independent of other actions on the gut mucosa. Staphylococcal food poisoning is one of the most commonly reported categories of foodborne disease. The organisms grow in warm food, primarily meat or dairy products, and produce the toxin. Onset of disease is usually within 2 to 6 hours of ingestion. *B. cereus* produces two toxins, one of which is preformed and is called the **emetic toxin,** because it produces vomiting. The second type, probably involving several enterotoxins, causes diarrhea. Often acquired from eating rice, *B. cereus* has also been associated with cooked meat, poultry, vegetables, and desserts.

Perhaps the most common cause of food poisoning is type A *C. perfringens,* which produces a neurotoxin in the host after ingestion. As a result, a relatively mild, self-limited (usually 24-hour) gastroenteritis occurs, often in outbreaks in hospitals. Meats and gravies are typical foods associated with this type of food poisoning.

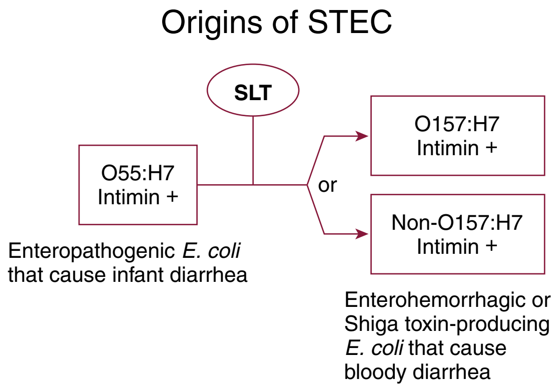
One of the most potent neurotoxins is produced by the anaerobic organism *Clostridium botulinum.* This toxin prevents the release of the neurotransmitter acetylcholine at the cholinergic nerve junctions, causing **flaccid** (rag doll) **paralysis.** The toxin acts primarily on the peripheral nerves but also on the autonomic nervous system. Patients exhibit descending symmetric paralysis and ultimately die of respiratory paralysis unless they are mechanically ventilated. In most cases, adult patients who develop botulism have ingested the preformed toxin in food (home-canned tomato products and canned, cream-based foods are often implicated), and the disease is considered intoxication, although

C. botulinum has been recovered from the stools of many adult patients. A relatively recently recognized syndrome, **infant botulism,** is a true GI infection. In adults, the normal microbiota probably prevents colonization by *C. botulinum,* whereas the organism can multiply and produce toxin in the infant bowel. Infant botulism is not uncommon; babies acquire the organism by ingestion, although the source of the bacterium is not always clear. Because an association has been found with honey and corn syrup, infants younger than 9 months of age should not be fed honey. The effect of the toxin is the same whether ingested in food or produced by growing organisms within the bowel.

Attachment. An organism's ability to cause disease can also depend on its ability to colonize and adhere to the bowel. To illustrate, ETEC must be able to adhere to and colonize the small intestine, as well as produce an enterotoxin. These organisms produce an adherence antigen, called **colonization factor antigen (CFA).** Certain strains of *E. coli* referred to as the enteropathogenic *E. coli* (EPEC) attach and then adhere to the intestinal brush border. This localized adherence is mediated by the production of pili. After attaching, EPEC disrupts normal cell function by effacing the brush epithelium, thereby causing diarrheal disease. This complete process is referred to as **attachment and effacement.** Genes responsible for the initial adherence of ETEC, STEC, and EPEC to intestinal epithelial cells reside on a transmissible plasmid. STEC has the same ability to attach to intestinal epithelial cells and cause effacement. In addition, STEC produces a Shiga toxin that spreads to the bloodstream, causing systemic damage to vascular endothelial cells of various organs, including kidney, colon, small intestine, and lung. STEC is believed to have arisen because of an EPEC strain that became infected with a bacteriophage carrying the Shiga toxin gene (Fig. 74.4).

Giardia duodenalis, a parasite, has increasingly become more common as an etiologic agent of GI disease in the United States. Excreted into fresh water by natural animal hosts such as the beaver, the organism can be acquired by drinking stream water or even city water in some localities, particularly in the Rocky Mountain region. The organism, a flagellated protozoan, adheres to the intestinal mucosa of the small bowel by means of a ventral sucker, destroying the mucosal cells' ability to participate in normal secretion and absorption. No evidence indicates invasion or toxin production.

Cryptosporidium and *Cystoisospora* spp., parasitic etiologic agents of diarrhea in animals and poultry and more recently recognized as causing human disease, probably also act by adhering to intestinal mucosa and disrupting function. Cryptosporidium are often seen in the diarrhea of patients with acquired immunodeficiency syndrome (AIDS), as well as in travelers' diarrhea, daycare epidemics, and diarrhea in people with animal exposure. *Cryptosporidium* and *Cystoisospora* spp. may cause severe, protracted diarrhea in AIDS patients. Other coccidian parasites, such as microsporidia, produce diarrhea by destroying intestinal cell function.



Origins of STEC
SLT

Non-O157:H7
Intimin +
Enteropathogenic *E. coli* that cause infant diarrhea
Enterohemorrhagic or Shiga toxin-producing *E. coli* that cause bloody diarrhea

• **Fig. 74.4** It appears that the presence of enterohemorrhagic *Escherichia coli (STEC)* strain O157:H7 was not simply overlooked before 1982. *E. coli* O157:H7 strains are closely related to a Shiga toxin–negative enteropathogenic *E. coli* (EPEC) strain O55:H7. It is proposed that this EPEC strain O55:H7 became infected by a bacteriophage that encoded Shiga toxin *(SLT)*; it is now recognized that at least 25 different virulence-associated genes may be associated with STEC and are classified into five "seropathotypes" A through E.

Invasion. After initial and essential adherence to GI mucosal cells, some enteric pathogens can gain access to the intracellular environment. Invasion allows the organism to reach deeper tissues, access nutrients for growth, and possibly avoid the host immune system.

In the case of diarrhea caused by *Shigella,* the primary mechanism of disease production consists of (1) the triggering and directing by *Shigella* entry into colonic epithelial cells by genes located on a plasmid, and once internalized, (2) the rapid multiplication of *Shigella* in the submucosa and lamina propria and the organism's intracellular and extracellular spread to other adjacent colonic epithelial cells. Once in the host cell cytoplasm, *Shigella* spp. cause apoptosis and release of the cytokines interleukin (IL)-1 and IL-8. The inflammatory response to these cytokines damages the colonic mucosa and exacerbates (aggravates) the infection. The genes for invasiveness are located on a large invasion plasmid. These activities lead to extensive superficial tissue destruction. If these two steps do not occur, the clinical presentation of classic dysentery does not develop (Table 74.3). The entry process is illustrated in Fig. 74.5.

Salmonellae interact with the apical (top) microvilli of colonic epithelial cells, disrupting the brush border. Similar to *Shigella, Salmonella* spp. also stimulate the host cell to internalize through rearrangements of host actin filaments and other cytoskeleton proteins. Once the whole bacteria are internalized within endocytic vesicles of the host epithelial cell, organisms begin to multiply within the vacuoles. In contrast to *Shigella* spp. that use the colonic mucosal epithelium as a site of multiplication, certain serotypes of *Salmonella,* such as *S. enterica* serovar Typhi, use the colonic epithelium as a route to gain access to the submucosal layers, mesenteric lymph nodes, and subsequently the bloodstream. The entry of *Salmonella* is a complex process involving several essential genes, as well as environmental conditions of the host cell; this process is still being delineated. Many virulence factors for invasion of salmonellae

TABLE 74.3 **Types of Enteric Infections**

Pathogenic Mechanism	Major Symptoms	Examples of Etiologic Agents
Upsetting of fluid and electrolyte balance/noninflammatory	Watery diarrhea No fecal leukocytes No fever	*Vibrio cholerae* Rotavirus Noroviruses Enteric adenoviruses Enterotoxigenic *Escherichia coli* *Giardia duodenalis* *Bacillus cereus*

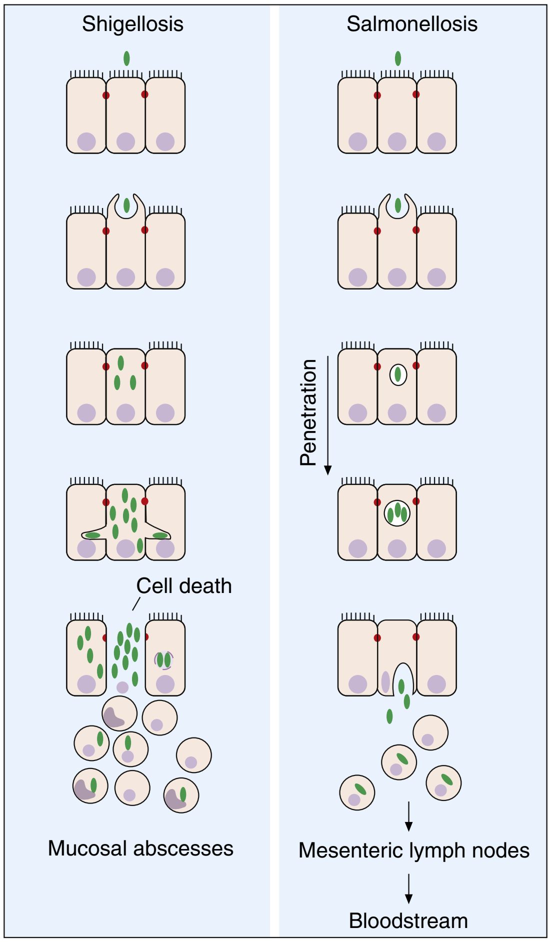
Penetration with subsequent access to the bloodstream (enteric fever)	Signs of systemic infection (headache, malaise, sore throat) Fever	*Salmonella enterica* serotype Typhi *Yersinia enterocolitica*



• **Fig. 74.5** The invasion of *Shigella* and *Salmonella* into intestinal epithelial cells. (Republished with permission of Oxford University Press from Sensonetti PJ. *Reviews of Infectious Diseases*. 1991;13[4].)

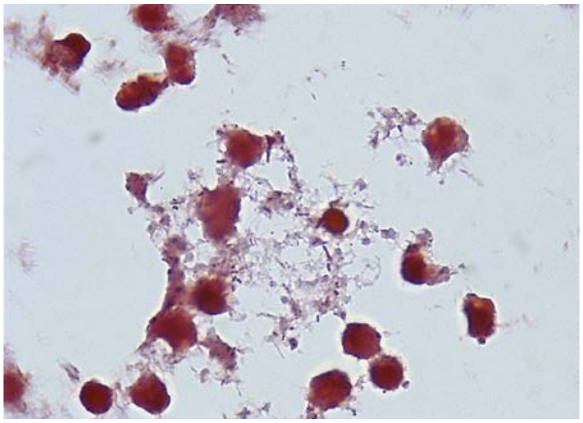
into nonphagocytic cells as well as their ability to cause systemic infections by surviving in phagocytic cells and replicating within the *Salmonella*-containing vesicle in a variety of eukaryotic cells are determined by chromosomal genes, many of which are located within pathogenicity islands. Invasiveness is also believed to contribute to the pathogenesis of disease associated with species of vibrios, campylobacters, *Yersinia enterocolitica, Plesiomonas shigelloides,* and *Edwardsiella tarda.*

Certain parasites, particularly *E. histolytica* and *Neobalantidium coli,* invade the intestinal epithelium of the colon. The ensuing amoebic dysentery is characterized by blood and numerous white blood cells, and the patient experiences cramping and tenesmus. Other parasites acquired by ingestion, such as *Trichinella,* may cause transient bloody diarrhea and pain during migration through the intestinal mucosa to their preferred sites within the host.

Other organisms selectively destroy absorptive cells (e.g., villus tip cells) in the mucosa, disrupting their normal cell function and thereby causing diarrhea. Rotaviruses and Norwalk-like viruses are both visualized by electron microscopy within the absorptive cells at the ends of the intestinal villi, where they multiply and destroy cellular function. As a result, the villi become shortened, and inflammatory cells infiltrate the mucosa, further contributing to the pathologic condition. In addition to these viral agents, hepatitis A, B, and C and occasionally enteric adenoviruses have been associated with diarrheal symptoms in patients.

Miscellaneous Virulence Factors

Other virulence traits appear to be involved in the development of GI infections and include characteristics such as motility, chemotaxis, and mucinase production. Also, the possession of certain antigens, such as the Vi antigen of



• **Fig. 74.6** Wright's stain of stool from a patient with shigellosis showing moderate numbers of polymorphonuclear cells.

S. enterica serotype Typhi and certain cell wall components, are also associated with virulence.

Clinical Manifestations

The clinical symptoms experienced by a patient are largely dependent on how the enteric pathogen causes disease. To illustrate, patients infected with an enteric pathogen that upsets fluid and electrolyte balance have no fecal leukocytes present in the stool and experience watery diarrhea; fever is usually absent or mild. Although nausea, vomiting, and abdominal pain may also be present, the dominant feature is intestinal fluid loss. In contrast, patients infected with an enteric pathogen that causes significant cell destruction and inflammation have fecal leukocytes present in the stool (Fig. 74.6). Their diarrhea is often characterized by the presence of mucus and blood; in many of these patients, fever is a prominent component of their disease, as are abdominal pain, cramps, and tenesmus. Finally, patients who become infected with a pathogen capable of penetrating the intestinal mucosa of the small intestine without producing enterocolitis and then subsequently spreading and multiplying at other sites will present with signs and symptoms of a systemic illness such as headache, sore throat, malaise, and fever; diarrhea in these patients is not a prominent feature and is absent or mild in many cases. Features of these three types of enteric infections are summarized in Table 74.3.

Epidemiology

GI infections occur in numerous epidemiologic settings. Awareness of these different settings is important because knowledge of an epidemiologic setting can help provide a basis for the diagnosis and clues to possible causes. When this knowledge is combined with clinical findings, the cause of the infection can often be narrowed to three or four organisms.

Institutional Settings

Diarrheal illness can be a major problem in institutional settings such as daycare centers, hospitals, and nursing homes. Because individual hygiene is often difficult to maintain in these settings, coupled with the presence of several organisms with relatively low infecting doses such as *Shigella* and *G. duodenalis,* numerous outbreaks of diarrheal illness caused by various organisms have been reported. Organisms such as *Shigella, C. jejuni* subsp. *jejuni, G. duodenalis, Cryptosporidium,* and rotaviruses have been reported to cause outbreaks in daycare centers. Of significance, these infections can be spread to family members. Similarly, outbreaks caused by these organisms, as well as hemorrhagic *E. coli* O157:H7, have been reported in nursing homes and other extended-care facilities.

Health care–associated (nosocomial) diarrheal illness is also a problem for patients and personnel in outpatient clinics, extended care facilities, and hospitals. Rotaviruses, adenoviruses, and coxsackie viruses have also been identified in health care–associated settings. In addition to these organisms, *C. difficile* is a major enteric pathogen that has been identified in outbreaks in hospitals and other settings, including nursing homes and extended-care facilities. This organism is a hardy pathogen that readily survives on **fomites** (inanimate objects) such as floors, bed rails, call buttons, and doorknobs and on the hands of hospital personnel caring for the patient. Of clinical concern is the emergence of a strain of *C. difficile* with increased virulence and fluoroquinolone resistance. By partial deletions in a toxin regulatory gene, *tad,* these isolates can produce 16- to 23-fold more toxin A and B. In addition, a separate binary toxin has been described that is encoded by *cdtA* and *cdtB* genes; *cdtB* mediates cell surface binding and cellular translocation, whereas *cdtA* disrupts the assembly of the actin filament, causing cell death. These strains have emerged as a cause of geographically dispersed outbreaks of *C. difficile*–associated disease. Many of the reported cases caused by these strains were in otherwise healthy patients with minimal or no exposure to a health care setting. *C. difficile* is the most common pathogen isolated in patients with antibiotic-associated diarrhea. However, **antibiotic-associated hemorrhagic colitis (AAHC)** is not linked to *C. difficile* infection (CDI). AAHC symptoms include a sudden onset of bloody diarrhea and abdominal cramps during antibiotic therapy. Toxin-producing *Klebsiella oxytoca* has been identified as a causative agent of AAHC.

Traveler's Diarrhea

Individuals who travel into developing geographic areas with poor sanitation are at particularly high risk for developing diarrhea. In areas with poor sanitation, enteric pathogens heavily contaminate the water and food. Although many types of enteric pathogens can cause diarrhea in travelers, ETEC is a leading cause in Asia, Africa, and Latin America, accounting for about 50% of cases. *Salmonella, Shigella, Campylobacter* spp., vibrios, rotavirus, and Norwalk virus can also cause diarrhea in travelers, depending on the area or country they visit.

Foodborne and Waterborne Outbreaks

The Centers for Disease Control and Prevention indicate that more than 48 million cases of foodborne illness are reported in the United States each year. Eating raw or undercooked fish, shellfish, or meats and drinking unpasteurized milk increases the risks of certain bacterial, parasitic, and viral infections. Many foodborne outbreaks can be traced to poor hygienic practices of food handlers such as not washing hands after using the toilet; hepatitis A, Norwalk virus, and *Salmonella* are a few examples of infectious agents and organisms that have contaminated food during preparation by a food handler and caused diarrheal disease. The number of cases of salmonellosis has gradually increased, with many of these infections associated with eating raw or undercooked eggs. Also, the potential for widespread dissemination of foodborne pathogens has increased because of factors such as the tendency to eat outside the home, the export and import of food sources worldwide, and travel.

In addition to foodborne outbreaks of GI tract infections, waterborne outbreaks of diarrheal disease caused by *G. duodenalis* and *Cryptosporidium* have been traced to inadequately filtered surface water. Recreational waters, including swimming pools, can also become contaminated with enteric pathogens such as *Shigella* and *G. duodenalis* because of poor toilet facilities or practices. Box 74.2 provides a listing of the more common GI syndromes, incubation period, and organisms associated with foodborne and waterborne illness.

Immunocompromised Hosts

GI tract infections in individuals infected with human immunodeficiency virus (HIV) and other patients who are immunosuppressed, such as organ transplant recipients or individuals receiving chemotherapy, are a diagnostic challenge for the clinician and microbiologist. For example, cytotoxic chemotherapy or antibiotic therapy may predispose patients to develop *C. difficile* colitis.

Diarrhea is a common clinical manifestation of infection with HIV. Numerous pathogens and opportunistic pathogens have been identified and are believed to cause recurrent or chronic diarrhea. Commonly reported etiologic agents include the following:

- Species of *Salmonella, Shigella,* and *Campylobacter*
- Cytomegalovirus
- *Cryptosporidium, Cystoisospora belli*
- Microsporidia
- *E. histolytica*
- *Mycobacterium* spp.
- *G. duodenalis*

Etiologic Agents

Many microorganisms can cause enteric infections. A discussion of each organism is beyond the scope of this chapter. Rather, these organisms are addressed in Parts III through VI of the textbook. Table 74.4 summarizes the general characteristics of the more common agents of enteric infections.

• BOX 74.2 Foodborne and Waterborne Gastrointestinal Syndromes

General Symptoms	Incubation/ Occurrence	Etiology
Nausea and vomiting	1–8 hours	*Staphylococcus aureus* *Bacillus cereus*
Abdominal cramps and diarrhea	8–16 hours	*Clostridium perfringens* *B. cereus*
Fever, abdominal cramps, and diarrhea	6–48 hours	*Salmonella* *Shigella* *Vibrio* *Campylobacter* *Escherichia coli* (STEC) *Yersinia enterocolitica*
Abdominal cramps and watery diarrhea	16–72 hours	*Listeria monocytogenes* *E. coli* (ETEC) *Vibrio*
Vomiting and nonblood diarrhea	10–51 hours	Noroviruses
Fever, abdominal cramps, with or without diarrhea	1–11 days	*Y. enterocolitica*
Bloody diarrhea with low fever	3–8 days	STEC
Paralysis	18–36 hours	*Clostridium botulinum*[a]
Persistent diarrhea	1–3 weeks	Parasitic *Cryptosporidium* *Giardia* *Cyclospora*
Systemic illness		*Vibrio vulnificus* *Vibrio* spp. *Toxoplasma gondii* *Trichinella* spp.

[a] Approximately 50% of patients will present with nausea and vomiting, and 20% with diarrhea; others may demonstrate constipation.

Other Infections of the Gastrointestinal Tract

Besides causing disease in the small and large intestine, microorganisms can also infect other sites of the GI tract, as well as the GI tract's accessory organs.

TABLE 74.4 General Characteristics of Agents of Enteric Infections

Organism	Common Sources or Predisposing Condition	Distribution	Clinical Presentation	Predominant Pathogenic Mechanism	Fecal Leukocytes
Arcobacter spp.	Foodborne	Unknown	Watery diarrhea or chronic	Unknown	Unknown
Bacillus cereus	Meats, vegetables, rice	Worldwide	Intoxication: vomiting or watery diarrhea	Ingestion of preformed toxin (food poisoning)	—
Clostridium botulinum	Improperly preserved vegetables, meat, fish	Worldwide	Neuromuscular paralysis	Ingestion of preformed toxin (food poisoning)	—
Staphylococcus aureus	Meats, salads, dairy products	Worldwide	Intoxication: vomiting	Ingestion of preformed toxin (food poisoning)	—
Clostridium perfringens	Meats, poultry	Worldwide	Watery diarrhea	Ingestion of organism followed by toxin production	—
Aeromonas	Water	Worldwide	Watery diarrhea, dysentery, and chronic diarrhea	Heat-labile cytotoxic enterotoxin (*alt* gene) and/or heat-stable cytotoxic enterotoxin (*ast* gene)	—
Campylobacter spp.	Water, poultry, milk	Worldwide	Dysentery	Invasion	+
Clostridioides difficile	Antimicrobial therapy; immunosuppression, underlying gastrointestinal disease, health care–associated exposure	Worldwide	Dysentery	Enterotoxin and cytotoxin	+/–
Diarrheagenic *Escherichia coli*					
Enteropathogenic (EPEC)		Worldwide	Watery diarrhea	Adherence/invasion without multiplication	—
Enterotoxigenic (ETEC)	Food, water	Worldwide—more prevalent in developing countries	Watery diarrhea	Enterotoxin	—
Enteroinvasive (EIEC)	Food	Worldwide	Dysentery	Invasion, enterotoxin	+
Enterohemorrhagic (STEC)	Meats	Worldwide	Watery, often bloody diarrhea	Cytotoxin	–/+
Plesiomonas shigelloides	Fresh water, shellfish	Worldwide	Watery, invasive dysentery-like, and subacute/chronic	Enterotoxins: *in vitro* Demonstration of cholera-like toxin, thermostable and thermolabile toxins, beta-hemolysins and cytotoxins	+/–
Salmonella spp. (nontyphoidal)	Food, water	Worldwide	Dysentery	Invasion	+

TABLE 74.4 **General Characteristics of Agents of Enteric Infections—cont'd**

Organism	Common Sources or Predisposing Condition	Distribution	Clinical Presentation	Predominant Pathogenic Mechanism	Fecal Leukocytes
Salmonella enterica serovar Typhi	Food, water	Tropical, developing countries	Enteric fever	Penetration	+ (monocytes, not PMNs)
Shigella spp.	Food, water	Worldwide	Dysentery	Invasion	+
Shigella dysenteriae	Water	Tropical, developing countries	Dysentery	Invasion, cytotoxin	+
Vibrio cholerae	Water, shellfish	Asia, Africa, Middle East, South and North America (along coastal areas)	Watery diarrhea	Enterotoxin, cytotoxin	−/+
Yersinia enterocolitica	Milk, pork, water	Worldwide	Watery diarrhea, and/or enteric fever	Invasion, penetration	—
Giardia duodenalis	Food, water	Worldwide	Watery diarrhea	Unknown—impaired absorption	—
Cryptosporidium parvum	Animals, water	Worldwide	Watery diarrhea	Adherence	—
Entamoeba histolytica	Food, water	Worldwide (more common in developing countries)	Dysentery	Invasion, cytotoxin	−/+ (amoebae destroy the white cells)
Rotavirus	Person-to-person; viral shedding often occurs during subclinical presentation and after cessation of diarrhea	Worldwide	Watery diarrhea	Mucosal damage leading to impaired absorption in small intestine; can be life-threatening	—
Enteric adenoviruses	Day care settings and health care–associated settings (hospitals); immunocompromised patients, particularly hematopoietic stem cell transplant recipients	Worldwide	Sporadic cases; chronic watery or subclinical presentation	Unknown	—
Astroviruses	Unknown	Worldwide	Pediatric gastroenteritis or asymptomatic in all ages; watery diarrhea	Unknown	—
Noroviruses (Caliciviruses)	Shellfish, salads Immunohematology ABH secretors and Lewis histo-blood groups serve as viral receptors	Worldwide	Watery diarrhea	Mucosal damage leading to impaired absorption in small intestine	–

ABH, A, B, and H, blood group antigens; *PMN*, Polymorphonuclear cells.

Esophagitis

Infections of the mucosa of the esophagus (**esophagitis**) can cause painful or difficult swallowing or the sensation that something is lodged in the throat while swallowing. Individuals who have esophagitis usually have local or systemic underlying illnesses such as hematologic malignancies or HIV infection, or they are receiving immunosuppressive therapy. The most common etiologic agents are *Candida* spp. (primarily *C. albicans*), herpes simplex virus, and cytomegalovirus.

Diagnosis of esophagitis is primarily based on the appearance of *Candida* spp. on a smear collected by an endoscopic brushing or biopsy of the esophagus. The smears may be examined by Gram stain, calcofluor white, or silver stain. Samples may also be submitted for histologic examination or viral culture.

Gastritis

Gastritis refers to inflammation of the gastric mucosa. This illness is associated with nausea and upper abdominal pain; vomiting, burping, and fever may also be present. A curved organism called *Helicobacter pylori* is seen on the surface of gastric epithelial cells of patients with gastritis. The organism is recovered from gastric biopsy material obtained endoscopically but not from stool. After acute infection, *H. pylori* can persist for years in most individuals, with many remaining asymptomatic. *H. pylori* is also the causative agent of peptic ulcer disease and a significant risk factor for the development of stomach cancer.

Proctitis

Proctitis is the inflammation of the rectum (distal portion of the large intestine). Common symptoms associated with proctitis are itching and a mucous discharge from the rectum; if the infection progresses, ulcers and abscesses may form in the rectum. Most infections are sexually transmitted through anal intercourse. *Chlamydia trachomatis,* herpes simplex, *Treponema pallidum,* and *Neisseria gonorrhoeae* are the most common etiologic agents.

Miscellaneous

Unusual agents and those that have not been cultured, such as mycobacteria that may be associated with Crohn disease and the bacterium associated with Whipple disease, *Tropheryma whipplei,* are also candidates as etiologic agents of GI disease. *T. whipplei* forms intracellular clusters within vacuoles of phagocytic cells or as extracellular bacteria. The organism is widespread in the environment and is associated with a high rate of human colonization. The human immune response generally results in clearance of the organism unless there is an immune deficiency resulting in predisposition for disease. Whipple disease typically occurs years after initial infection with *T. whipplei,* resulting in chronic diarrhea and migratory arthralgia of the joints. Central nervous system damage may occur, resulting in poor prognosis and antibiotic treatment failure.

Occasionally, stool cultures from patients with diarrheal disease yield heavy growth of organisms such as enterococci, *Pseudomonas* spp., or *Klebsiella pneumoniae,* not usually found in such numbers as normal microbiota. Only anecdotal evidence suggests that these organisms contribute to the pathogenesis of the diarrhea. Agents of sexually transmitted disease may cause GI symptoms when they are introduced into the colon via sexual intercourse. *Mycobacterium intracellulare* may be sexually transmitted, resulting in systemic disease in patients with AIDS. The pathogenesis of infections resulting from *Blastocystis hominis* (a possible coccidian etiologic agent of human diarrheal disease) is not well documented, although these organisms are associated with GI symptoms. Epidemiologic studies indicate that the organism is likely the pathogen when present in high numbers in the presence of GI disease and the absence of other etiologic agents.

Laboratory Diagnosis of Gastrointestinal Tract Infections

Specimen Collection and Transport

If enteric pathogens are to be detected by the laboratory, adherence to appropriate guidelines for specimen collection and transport is imperative (see Table 5.1 for a quick guide to specimen collection, transport, and processing). Stool (feces) specimens and rectal swabs are often submitted for the identification of the pathogen associated with diarrhea or food poisoning. If an etiologic agent is not isolated with the first culture or visual examination, two additional specimens should be submitted to the laboratory over the next few days. Because organisms may be shed intermittently, collection of specimens at different times over several days enhances recovery. Certain infectious agents, such as *Giardia,* may be difficult to detect, requiring the processing of multiple specimens over weeks, duodenal aspirates (in the case of *Giardia*), or additional alternative methods.

General Comments

Stool specimens submitted for the identification of enteric pathogens and delivered to the laboratory within 30 minutes may be collected in a clean plastic container. The samples should not be contaminated with urine, barium, or toilet paper. Rectal swabs should be placed in transport medium such as Stuart's. Stool for direct wet-mount examination, *C. difficile* toxin assay, and ELISA or the latex agglutination test for rotavirus must be sent to the laboratory without any added preservatives or liquids. Volume of a liquid stool at least equal to 1 teaspoon (5 mL) or a pea-sized piece of formed stool is necessary for most procedures. Nucleic acid–based GI panels for the identification of enteric pathogens including viral agents should be collected as described by the manufacturer.

Stool Specimens for Bacterial Culture

If a delay longer than 2 hours is anticipated for stools for bacterial culture, the specimen should be placed in transport medium. The Cary-Blair transport medium preserves the viability of intestinal bacterial pathogens, including *Campylobacter* and *Vibrio* spp. However, the media produced by different manufacturers can vary. Most workers recommend reducing the agar content of Cary-Blair medium from 0.5% to 0.16% (modified) for maintenance of *Campylobacter* spp. Buffered glycerol transport medium does not maintain these bacteria. Additional transport media, such as alkaline peptone water, is preferred for the isolation of *V. cholerae.* Several manufacturers produce a small vial of Cary-Blair with a self-contained plastic scoop suitable for collecting samples.

Because *Shigella* spp. are sensitive to environmental factors, a transport medium of equal parts of glycerol and 0.033 M phosphate buffer (pH 7.0) increases the viability of *Shigella* compared with Cary-Blair. For this purpose, maintaining the glycerol transport medium at refrigerator or freezer temperatures also improves recovery.

If a patient did not enter the hospital with GI symptoms but develops diarrhea more than 3 days after admission, careful consideration of the potential etiologic agent being an enteric pathogen or virus other than *C. difficile* is unlikely. However, community-acquired CDI does occur after hospital discharge or another outpatient treatment. Therefore, outpatient samples submitted for culture or nucleic acid testing for *C. difficile* should not be rejected. However, if initial testing is negative, repeat testing is not warranted.

Stool Specimens for Ova and Parasites

For detection of ova and parasites, specimen preservation with a fixative is recommended for visual examination (Chapter 46).

Stool Specimens for Viruses

Stools for virus culture must be refrigerated if they are not inoculated into cell cultures within 2 hours. A rectal swab, transported in modified Stuart's transport medium or another viral transport medium, is adequate for recovery of most viruses from feces. See Chapter 64 for more information regarding the collection and transport of specimens for viral culture. Samples collected for use in nucleic acid–based testing should follow the manufacturer's recommended procedures.

Miscellaneous Specimen Types

Other specimens that may be obtained for diagnosis of GI tract infection include duodenal aspirates. These samples should be examined immediately using direct microscopy for the presence of motile protozoan trophozoites, cultured for bacteria, and placed into polyvinyl alcohol (PVA) fixative for subsequent parasitic examination. The laboratory should be informed in advance so that the specimen can be processed and examined efficiently.

The string test has proved useful for diagnosing duodenal parasites, such as *Giardia,* and for isolating *S. enterica* serotype Typhi from carriers and patients with acute typhoid fever. This test is still used in underdeveloped countries worldwide. The patient swallows a weighted gelatin capsule containing a tightly wound length of string, which is left protruding from the mouth and taped to the cheek. After a predetermined period, during which the capsule reaches the duodenum and dissolves, the string, now covered with duodenal contents, is retracted and delivered immediately to the laboratory. The microbiologist strips the mucus and secretions attached to the string and deposits some material on slides for direct examination and some material into fixative for preparation of permanent stained mounts. The microbiologist also inoculates some material to appropriate media for isolation of bacteria.

Direct Detection of Agents of Gastroenteritis in Feces

Wet Mounts

A direct wet mount of fecal material, particularly with liquid or unformed stool, is the fastest method for detecting motile trophozoites of *Dientamoeba fragilis, Entamoeba, Giardia,* and other intestinal parasites. Occasionally the larvae or adult worms of other parasites may be visualized. Experienced observers can also see the refractile forms of *Cryptosporidium* and many types of cysts on the direct wet mount, including *Cyclospora cayetanensis,* a parasite that is associated with the consumption of contaminated food such as raspberries. If present in sufficient numbers, the ova of intestinal parasites can be seen.

Examination of a direct wet mount of fecal material containing blood or mucus, with the addition of an equal portion of Loeffler methylene blue, is helpful for detection of leukocytes, which occasionally aids in differentiating among the various types of diarrheal syndromes. Infectious inflammatory diarrhea caused by enteric pathogens will present as leukocyte-positive, whereas secretory diarrhea associated with toxin-producing organisms, viruses, and protozoans will present as leukocyte-negative. In addition, fecal leukocytes degrade rapidly and may make identification and quantification difficult. Another commercially available test detects lactoferrin, which is a glycoprotein released from neutrophil granules into the stool sample. This assay demonstrates improved sensitivity and specificity compared with detection of intact WBCs. A sample that appears lactoferrin-positive is considered positive for the presence of fecal leukocytes. Under phase-contrast and dark-field microscopy, the darting motility and curved forms of *Campylobacter* may be observed in a warm sample. Water or saline, which will immobilize *Campylobacter,* should not be used. However, for practical reasons most laboratories do not use a wet mount.

Stains

Feces may be Gram stained for detection of certain etiologic agents. For example, many thin, comma-shaped, gram-negative bacilli may indicate *Campylobacter* infection (if vibrios have been ruled out). In addition, polymorphonuclear cells may also be detected. An acid-fast stain can be used to detect *Cryptosporidium* spp., mycobacteria, and *Cystoisospora* spp. Examination of fixed fecal material for parasites by trichrome or other stains is covered in Chapter 46. A permanent stained preparation should be made from all stool specimens received for detection of parasites.

Antigen Detection

Enzyme immunoassays (EIAs) can detect numerous microorganisms capable of causing GI tract infections. For example, EIAs are commercially available to detect *E. coli* O157:H7 and *Campylobacter* spp., the presence of the Shiga toxins produced by STEC, or the presence of *C. difficile* toxins A or A and B. In addition, rotavirus is detected using a solid-phase EIA procedure. EIA methods are also available for detection of antigens of *Cryptosporidium* and *G. duodenalis* as well as *E. histolytica.* EIA methods have also been evaluated for detection of certain bacterial pathogens. Laboratory diagnosis of *C. difficile* uses EIA or latex agglutination kits coupled with glutamate dehydrogenase (GDH) and A/B toxin in a combination assay.

Nucleic Acid Testing

The development of amplification techniques has led to numerous publications for the direct detection of many enteric pathogens, including all major organism groups—bacteria, viruses, and parasites. Nucleic acid–based testing is available for a large variety of pathogens such as *C. difficile, Campylobacter* spp., staphylococci, and enterococci including antibiotic-resistant determinants and additional viral agents associated with GI disease. It is important to note that some studies indicate that concordance between phenotypic and molecular diagnostic panels vary. The accuracy for the detection of *Salmonella* spp. in nucleic acid testing methods has been shown to not be as effective as traditional methods. In addition, failure to maintain cultures of GI isolates that have been identified using nucleic acid–based methods presents a new challenge. The organism itself is not available for susceptibility testing if required, which is very important for certain bacterial pathogens (e.g., *Shigella*) for which susceptibility patterns vary. This is reducing the amount of epidemiological data available to monitor trends and patterns in antibiotic sensitivity patterns in GI pathogens. The implementation of whole genome sequencing for molecular epidemiology in diagnostic laboratories will improve the gaps that have been created by using culture independent methods for the diagnosis of GI infections.

Culture of Fecal Material for Isolation of Etiologic Agents

Bacteria

Fecal specimens for culture should be inoculated to several media for maximal yield, including solid agar and broth. The choice of media is based on the requirements of the clinician, the geographic region, the patient population, known endemic infectious agents, and the laboratory. Recommendations for a standardized selection of media are included in this section; however, each laboratory should consider the factors previously listed to determine the most efficient isolation and diagnostic methods offered in the facility.

Organisms for Routine Culture

Stool received for routine culture in most clinical laboratories in the United States should be examined for the presence of *Campylobacter, Salmonella,* and *Shigella* spp. under all circumstances. Detection of *Aeromonas* and *Plesiomonas* spp. should be incorporated into routine stool culture procedures. The cost of doing a stool examination on every patient for all potential enteric pathogens is prohibitive. The decision as to what other bacteria are routinely cultured should consider the incidence of GI tract infections caused by etiologic agents in the area served by the laboratory. For example, if the incidence of *Y. enterocolitica* gastroenteritis is high enough in the area served by the laboratory, then this agent should also be sought routinely. Similarly, because of the increasing prevalence of disease caused by *Vibrio* spp. in individuals living in high-risk areas of the United States (sea coast), laboratories in these localities may routinely look for these organisms. Conversely, unless a patient has a significant travel history, a laboratory located in the Midwestern United States should not routinely look for these organisms except by special request. Protocols for culture of enterohemorrhagic *E. coli* (e.g., *E. coli* O157:H7) vary greatly; based on incidence of disease, laboratories routinely use non–culture-based methods for this organism when cases of severe diarrhea are implicated. Selective or screening media to detect *E. coli* O157:H7 also vary greatly, including using a 1% sorbitol-containing medium (most O157:H7 *E. coli* are sorbitol-negative), a specific trypticase blood agar (Unipath GmbH, Wesel, Germany), Ramba CHROM (Gibson Laboratories, LLC, Lexington, KY), CHROMagar (BD Diagnostics, Franklin Lakes, NJ), or Rainbow Agar O157 (Bio-log, Inc., Hayward, CA).

Routine Culture Methods

An in-depth discussion regarding culture of all enteric pathogens is beyond the scope of this chapter. Because U.S. laboratories are routinely using non–culture-based methods for the identification of enteric bacterial pathogens, laboratories should consider performing reflux cultures on enteric pathogens for further characterization, changing trends in diagnostic practices, and surveillance studies. As culture independent methods evolve, including whole genome sequencing availability, diagnostic practices will continue to evolve, and the need for culturing these organisms may not be necessary. Laboratories should routinely examine stools for the presence of *Salmonella, Shigella,* and *Campylobacter* spp., therefore, culture of these organisms is addressed. Culture conditions for all other pathogens, including viruses, are covered in Parts III, IV, and VI. Specimens received for detection of the most commonly isolated Enterobacterales and *Salmonella* and *Shigella* spp. should be plated to a supportive medium, a slightly selective and differential medium, and a moderately selective medium.

Blood agar (tryptic soy agar with 5% sheep blood) is an excellent general supportive medium. Blood agar medium allows growth of yeast species, staphylococci, and enterococci, in addition to gram-negative bacilli. The absence of normal gram-negative fecal microbiota or the presence of significant quantities of organisms such as *S. aureus,* yeasts, and *Pseudomonas aeruginosa* can be evaluated. The use of blood agar also provides colonies for oxidase testing. Several colonies that do not resemble *Pseudomonas* spp. from the third or fourth quadrant should be routinely screened for production of cytochrome oxidase. If numerous colonies are present, *Aeromonas, Vibrio,* or *Plesiomonas* spp. should be suspected.

The slightly selective agar should support growth of most Enterobacterales, vibrios, and other possible pathogens; MacConkey agar works well. Some laboratories use eosin-methylene blue (EMB), which demonstrates a slight increase in inhibition of contaminating microorganisms. All lactose-negative colonies should be tested further, ensuring adequate detection of vibrios and pathogenic Enterobacterales. Lactose-positive vibrios *(V. vulnificus),* pathogenic *Escherichia* spp. (particularly *E. coli*), some *Aeromonas* spp., and *Plesiomonas* spp. may not be distinctive on MacConkey agar.

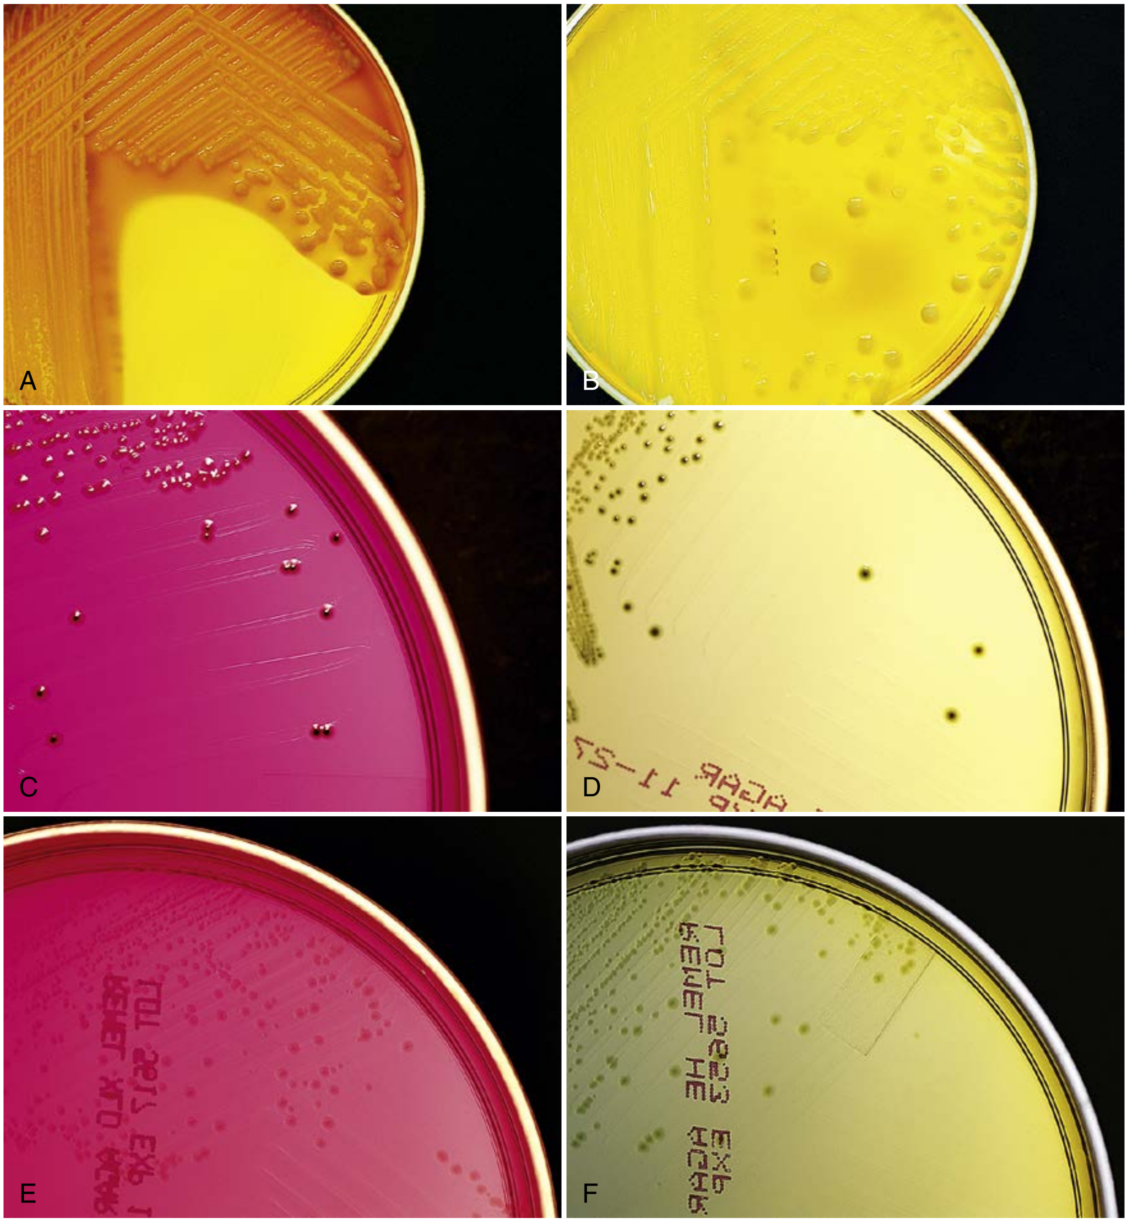
***Salmonella* and *Shigella*.** Maximum recovery of *Salmonella* and *Shigella* is obtained when inoculating an enrichment broth in addition to primary direct plating of specimens. The selective enrichment using selenite broth is commonly used for both organisms. Gram-negative broth may also be used in some laboratories as an enrichment media for the isolation of *Shigella* spp. Selenite-F broth can be used for the isolation and enrichment of *Salmonella* spp. Selenite broth base with mannitol is used for *S. enterica* serotype Typhi and *S. enterica* serotype Paratyphi. The specimen should also be inoculated to a moderately selective agar such as Hektoen enteric (HE), xylose-lysine deoxycholate (XLD) media, or CHROMagar *Salmonella*. HE and XLD are used in many laboratories because both *Salmonella* and *Shigella* can be isolated using these agars. Cultures suspected of isolation for *S. enterica* serotype Typhi should include a highly selective medium such as brilliant green agar or bismuth sulfite agar. These media inhibit growth of most Enterobacterales, allowing *Salmonella* and *Shigella* spp. to be detected. Colony morphologies of lactose-negative, lactose-positive, and H_2S-producing organisms are illustrated in Fig. 74.7. All these media are incubated at 35°C to 37°C in ambient air and examined at 24 and 48 hours for suspicious colonies.

***Campylobacter*.** Cultures for isolation of *C. jejuni* and *Campylobacter coli* should be inoculated to a combination of at least two selective agars containing antimicrobial agents that suppress the growth of normal microbiota. The introduction of a blood-free, charcoal-containing medium containing selective antibiotic components has improved recovery of most enteropathogenic *Campylobacter* spp. There are two primary formulations commercially available: charcoal cefoperazone deoxycholate agar (CCDA) and charcoal-based selective medium (CSm). Blood-containing medium, Skirrow medium, and Campy-CVA (cefoperazone, vancomycin, amphotericin) are also available. *Brucella* broth base has yielded less satisfactory recovery of *Campylobacter* spp. Blood-free formulations are reported to have better performance for the isolation of *Campylobacter* spp. from stool specimens. Commercially produced agar plates for isolation of campylobacters are available from several manufacturers. These plates are incubated in a microaerophilic atmosphere at 42°C and examined at 24 and 48 hours for suspicious colonies. Culture methods for other campylobacters associated with GI disease, such as *C. hyointestinalis* subsp. *hyointestinalis* and *C. fetus* subsp. *fetus,* are provided in Chapter 33.

Enrichment Broths. As previously indicated, enrichment broths are sometimes used for enhanced recovery of *Salmonella, Shigella, Campylobacter,* and *Y. enterocolitica,* although *Shigella* usually does not survive enrichment. Gram-negative broth (Hajna GN) or selenite F broth yields good recovery for most routine cultures. Enrichment broths for Enterobacterales should be incubated in air at 35°C for 6 to 8 hours, and then several drops should be subcultured to at least two selective media. Stool specimens would be inoculated to broth initially along with plating to primary culture media; those broths that test negative (demonstrate no growth) could be discarded without subculturing. Campy-thioglycollate enrichment broth increases the yields of positive cultures for *Campylobacter* spp., although it is not necessary for routine use. Enrichment broth for *Campylobacter* is refrigerated overnight or for a minimum of 8 hours before a few drops are plated to *Campylobacter* agar and incubated at 42°C in a microaerophilic atmosphere.

Laboratory Diagnosis of *Clostridioides difficile*–Associated Diarrhea

The definitive diagnosis of *C. difficile*–associated diarrhea is based on clinical criteria combined with laboratory testing. Visualization of a characteristic pseudomembrane or plaque on colonoscopy is diagnostic for PMC and, with the appropriate history of prior antibiotic use, meets the criteria for diagnosis of antibiotic-associated PMC. Additional patient risk factors should also be considered for potential diagnosis for CDI, such as advanced age (>65 years), immunosuppression or other severe underlying GI disease, use of proton pump inhibitors, and exposure to a health care setting. No single laboratory test will establish the diagnosis unequivocally. Two major types of tests are available for routine use: culture for direct detection of the organism and detection of cytotoxin (toxin A, B, or both) by cell culture cytotoxicity neutralization or EIA. In addition, most laboratories are using nucleic acid–based testing methods. Some of the commercially available nucleic acid–based assays include BD Gene Ohm (BD Diagnostics, La Jolla, CA), Cepheid Xpert (Cepheid, Sunnyvale, CA), FilmArray (BioFire Diagnostics Inc., Salt Lake City, UT), Roche LightCycler (Roche Applied Science), and ProGastro (Hologic, San Diego, CA). Nucleic acid–based testing demonstrates high sensitivity and specificity for the diagnosis of *C. difficile*–associated diarrhea. Diagnosis of a CDI should include a method to identify the organism and a method to assess the toxin status including immunoassay for either toxin A or B, cell culture cytotoxicity, or a nucleic acid method for the detection of toxin B. This prevents an incorrect diagnosis of clinical disease and administration of unnecessary medications or antibiotics in a patient colonized with a nontoxigenic strain.



• **Fig. 74.7** Colonies of a lactose-positive organism growing on xylose-lysine deoxycholate (XLD) agar (A) and Hektoen enteric (HE) agar (B). Colonies of *Salmonella enteritidis* (lactose-negative) growing on XLD (C) and HE agar (D). (Note how both agars detect H_2S production.) Colonies of *Shigella* (lactose-negative) growing on XLD (E) and HE agar (F).

CASE STUDY 74.1

A 30-year-old male developed diarrhea with severe abdominal cramping 3 days after eating in a local restaurant. He became febrile and weak and went to his physician. A stool specimen was collected and immediately hand-carried to the laboratory. Numerous white blood cells and bacteria were seen in a wet mount, but the bacteria were noteworthy in that they were nonmotile. The patient was treated with ciprofloxacin. A culture was performed that grew a non–lactose-fermenting gram-negative rod that was identified as *Shigella sonnei*.

Questions

1. What agent of diarrhea becomes nonviable in a stool that has not been cultured within 30 minutes of collection?
2. If the culture is going to be delayed in transit, what preservative and storage temperature is best for preservation of the specimen?
3 After culturing the organism, what traditional method is used to identify *Shigella* to the species level, and what is the importance of such identifications?

CASE STUDY 74.2

A 52-year-old female on immune-suppressive therapy for rheumatoid arthritis presents with a 2-day history of severe, watery diarrhea. This is accompanied by chills and reported fever of 101°F. She has no complaints of nausea or myalgia, but she does have severe abdominal cramps and loss of appetite. She had recently visited her niece, who had just purchased a pet turtle. She reports no other significant travel history or ill contacts and is treated with antidiarrheal medications as an outpatient.

On the third day of illness she returns in a worsening condition with the following physical examination and laboratory results:

- Vitals: Temp 102°F, respiration 20, BP 90/56, pulse 98
- Examination is essentially unremarkable with exception of diffusely tender abdomen; there is no rash or adenopathy, and the patient appears dehydrated
- WBC 16K (reference range 5–10 × 10^9/L) with 82% granulocytes
- Hgb = 14.5
- Liver function tests: amylase, lipase are all normal
- Sodium is 144 (reference range 135–145 mEq/L)
- K = 3.0 (reference range 3.6–5.0 mEq/L)

She is admitted to the hospital for rehydration, potassium replacement, and additional investigation. The initial diagnosis is sepsis syndrome. Because diarrhea is the major feature of her illness, a stool sample is submitted for culture and fecal WBC count.

The patient rapidly convalesced by the second day of admission on empiric triple antibiotic therapy. While the patient was hospitalized, her niece became ill with severe diarrhea and was successfully treated as an outpatient.

Questions

1. What is the likely agent of infection in this case?
2. Did the administration of antibiotics improve or worsen the patient's condition? Explain your answer.
3. Why did the niece recover so quickly, whereas the initial patient suffered a much more severe disease including dehydration and sepsis?

Chapter Review

1. Self-limiting food poisoning is often a result of ingestion of:
   a. *C. botulinum* spores
   b. Contaminated hamburger containing *E. coli*
   c. Salads or other foods contaminated with *S. aureus*
   d. *V. cholerae*–contaminated water

2. What does enterotoxic diarrheal disease produce?
   a. Bloody mucus–containing diarrhea
   b. Profuse watery stool
   c. Increased fecal WBC counts
   d. Bloody diarrhea

3. Repression of normal microbiota by the intake of antimicrobials often results in a GI infection with:
   a. Enteropathogenic *E. coli*
   b. *P. aeruginosa*
   c. *C. difficile*
   d. *Candida albicans*

4. All the following protect the GI tract from infection *except:*
   a. Peristaltic movement
   b. Resident bacterial microbiota
   c. Mucus
   d. Alkaline pH

5. A patient presented with headache and malaise and is slightly emaciated. The patient indicates that she has had watery diarrhea for approximately 24 hours. The infection is most likely:
   a. A result of infection with *Shigella* sp.
   b. Infection in the small intestine
   c. Infection in the large intestine
   d. A result of infection with *E. coli*

6. Several tests are available for the detection of enterotoxin, including which of the following?
   a. Immunodiffusion, serology, culture
   b. Immunodiffusion, latex agglutination, or molecular (gene identification)

- **c.** PCR, immunodiffusion, culture
- **d.** Culture followed by serology

7. Which organism is associated with thrombotic thrombocytopenia purpura?
- **a.** *S. dysenteriae*
- **b.** *C. difficile*
- **c.** STEC
- **d.** *V. cholerae*

8. Which of the following is a flagellated protozoan that attaches to the intestine via a ventral sucker?
- **a.** *Cryptosporidium*
- **b.** *Cystoisospora* spp.
- **c.** *Strongyloides stercoralis*
- **d.** *G. duodenalis*

9. A patient presents to the emergency room with fever and bloody, mucus-laden diarrhea. The patient is complaining of abdominal cramping. What is the likely agent of infection?
- **a.** *Salmonella*
- **b.** *E. coli*
- **c.** *Shigella*
- **d.** *C. difficile*

10. True or False

_____ *E. coli* O157:H7, *Shigella,* and *C. difficile* can withstand the exposure to gastric acids.

_____ Enterotoxigenic diarrhea is always the result of an infection with a GI pathogen.

_____ Failure to isolate any enteric pathogens in a stool is diagnostic for no evidence of infection.

_____ Stool specimens contain lots of debris, including plant material, metabolic by products, and bacteria, therefore negating the necessity for transport media.

11. Matching: *Match each term with the correct description.*

_____ *C. botulinum*
_____ *Salmonella*
_____ *C. jejuni*
_____ *C. difficile*
_____ ETEC
_____ *C. perfringens*
_____ *G. duodenalis*
_____ esophagitis
_____ *V. cholerae*
_____ *B. cereus*

a. health care–associated
b. rice
c. honey
d. eggs
e. microaerophilic
f. subunits A and B
g. heat-labile toxin
h. meats and gravies
i. traveler's diarrhea
j. HIV

12. Short Answer

(1) Describe a typical protocol for the media requirements used for culture identification of enteric pathogens. Why is it still important to culture enteric pathogens if molecular testing is used for identification?

(2) Describe the proper laboratory diagnosis for *C. difficile*–associated diarrhea.

75

Skin, Soft Tissue, and Wound Infections

OBJECTIVES

1. Identify the layers of the skin and describe the function of the skin in host defense, including the physical and chemical properties.
2. List the organisms that colonize the skin and are considered normal microbiota.
3. Describe the mechanisms that allow bacteria to invade and cause skin and soft tissue infections.
4. Define each of the following manifestations of skin infection:
   Macule
   Papule
   Nodule
   Pustule
   Vesicle
   Bulla
   Scales
   Ulcer
5. Characterize each of the following types of infection, and describe the associated laboratory diagnosis:
   Folliculitis
   Furuncle
   Carbuncle
   Erysipelas
   Erythrasma
   Erysipeloid
   Impetigo
   Cellulitis
   Dermatophytoses
   Necrotizing fasciitis
   Myositis
6. List an organism that commonly causes the following types of infection, and describe the associated laboratory diagnosis:
   Postoperative
   Bite
   Burn
7. Define sinus tract, including organisms associated with this condition.
8. Identify the pathogens most commonly associated with infections in patients with diabetes mellitus.
9. Describe and evaluate a specimen submitted for culture from the following types of infection: ulcers, nodules or abscess, pyoderma or cellulitis, vesicles or bullae, sinus tracts, fistula, burns, postsurgical wounds, and bite infections.
10. Correlate patient signs and symptoms with laboratory results to identify the etiologic agent associated with a skin, soft tissue, or wound infection.

General Considerations

The skin serves as a barrier between the internal organs and the external environment. Skin is subjected to frequent trauma and therefore is at risk of infection. In addition, manifestations visible on the surface of the skin can provide clues for the identification of an internal systemic disease.

Anatomy of the Skin

The skin is divided into two distinct layers: the **epidermis** (the outermost layer), and the **dermis.** The subcutaneous tissue beneath the dermis connects the skin to underlying structures (Fig. 75.1). The epidermis is made up of stratified squamous epithelium. **Hair follicles, sebaceous glands** (oil-producing), and **sweat glands** open to the skin surface through the epidermis. The dermis is composed of dense connective tissue rich in blood and nerve endings, and some hair follicles and sebaceous glands originate here. The **subcutaneous tissue** contains loose connective tissue and is rich in fat. Deeper hair follicles and sweat glands originate in this layer. Below the subcutaneous layer are thin **fascial membranes** (sheets or bands of fibrous tissue) covering muscles, ligaments, and other connective tissue.

Function of the Skin

The skin is the body's largest and thinnest organ. It forms a self-repairing and protective boundary between the body's internal environment and the external environment. Skin plays a crucial role in the control of body temperature, excretion of water and salts, synthesis of important chemicals and hormones, and as a sensory organ. The skin has an important protective function because of the composition of the outermost layer of the epidermis, which is composed of cells containing **keratin,** a water-repellent protein. The skin's normal microbiota, pH, and chemical defenses (high salt and acidic environment) also help prevent colonization by many pathogens. Examples of resident microbiota are listed in Box 75.1, although variation can occur among people.

Cutibacterium acnes

Prevalence, Etiology, and Pathogenesis

Approximately 15% of all patients who seek medical attention have either some skin disease or a skin lesion, many of which are infectious. Various bacteria, fungi, parasites, and viruses may be involved. These infections can include one or several causative agents. Because of the diversity of etiologic agents and the potential complexity of these infections, only the most common infections involving the skin and subcutaneous tissues will be addressed.

Skin infections can arise from the invasion of certain organisms from the external environment through breaks in the skin or from organisms that reach the skin through the blood as part of a systemic disease. In some infections, such as staphylococcal scalded-skin syndrome, toxins produced by the bacteria cause skin lesions. In others, lesions are a result of the host's immune response to microbial antigens.

Because of the diversity of etiologic agents, clinicians will often rely on the appearance of skin lesions for diagnostic clues to determine the required laboratory testing. The physical characteristics of the lesions can indicate the need for smear, culture, biopsy, or surgical procedures. Some of the terms most commonly used to describe manifestations of skin infections are provided in Table 75.1. Fig. 75.2 shows examples of some skin lesions.

Skin and Soft Tissue Infections

Infections of the Epidermis and Dermis

Numerous infections of the skin may occur. Several of the most common are discussed here.

Infections in or Around Hair Follicles

Folliculitis, furuncles, and **carbuncles** are localized abscesses either in or around hair follicles. These infections are distinguished from one another based on size and the extent of involvement in subcutaneous tissues. Table 75.2 summarizes each infection's respective clinical features. For the most part, these infections are precipitated by blockage of the hair follicle with skin oils (**sebum**) or because of minor trauma resulting from friction, such as that caused by clothes rubbing against the skin. *Staphylococcus aureus* is the most common etiologic agent for all three infections. Members of the Enterobacterales, *Malassezia furfur*, and *Candida* spp. may also cause folliculitis. Outbreaks of folliculitis caused by *Pseudomonas aeruginosa* have been reported to be associated with the use of whirlpools, swimming pools, and hot tubs.

Infections in the Keratinized Layer of the Epidermis

Because of their ability to utilize the keratin in the epidermal cells, the dermatophyte fungi are significant and well-suited pathogens for infection. Unlike the previously discussed infections, dermatophytes do not invade the deeper layers of

TABLE 75.1 **Manifestations of Skin Infections**

Term	Description	Possible Etiologic Agents (Infections)
Macule	A circumscribed (limited), flat discoloration of the skin	Dermatophytes *Treponema pallidum* (secondary syphilis) Viruses, such as enteroviruses (exanthems rashes)
Papule	An elevated, solid lesion ≤5 mm in diameter	Human papillomavirus types 3 and 10 (flat warts) Pox virus (molluscum contagiosum) *Sarcoptes scabiei* (scabies) *Staphylococcus aureus, Pseudomonas aeruginosa,* etc. (folliculitis)
Nodule	A raised, solid lesion >5 mm in diameter	*Corynebacterium diphtheriae* *Sporothrix schenckii* Miscellaneous fungi (subcutaneous mycoses) *Mycobacterium marinum* *Nocardia* spp. *S. aureus* (furuncle)
Pustule	A circumscribed, raised, pus-filled (leukocytes and fluid) lesion	*Candida* spp. Dermatophytes Herpes simplex virus *Neisseria gonorrhoeae* (gonorrhea) *S. aureus* (folliculitis) *S. aureus* or group A streptococci (impetigo) Varicella-zoster virus (chickenpox)
Vesicle	A circumscribed, raised, fluid-filled (blisterlike) lesion ≤5 mm in diameter	Herpes simplex virus Varicella-zoster virus (chickenpox and shingles)
Bulla	A circumscribed, raised, fluid-filled lesion >5 mm in diameter	Clostridial species (necrotizing gas gangrene) Herpes simplex virus Other gram-negative bacilli *S. aureus* (bullous impetigo and scalded-skin syndrome) *Vibrio vulnificus* and other *Vibrio* spp.
Scales	Dry, horny, platelike lesions	Dermatophytes (tinea)
Ulcer	A lesion with loss of epidermis and dermis	*Bacillus anthracis* (cutaneous anthrax) Bowel microbiota (decubiti) *Haemophilus ducreyi* (chancroid) *T. pallidum* (chancre of primary syphilis)

Adapted from Lazar AJF. *Robbins Basic Pathology.* 8th ed. St Louis: Saunders; 2007.

skin. Because keratin is also present in hair and nails, these fungi may also cause superficial infections at these sites (see Chapter 60 for more information).

Infections in the Deeper Layers of the Epidermis and Dermis

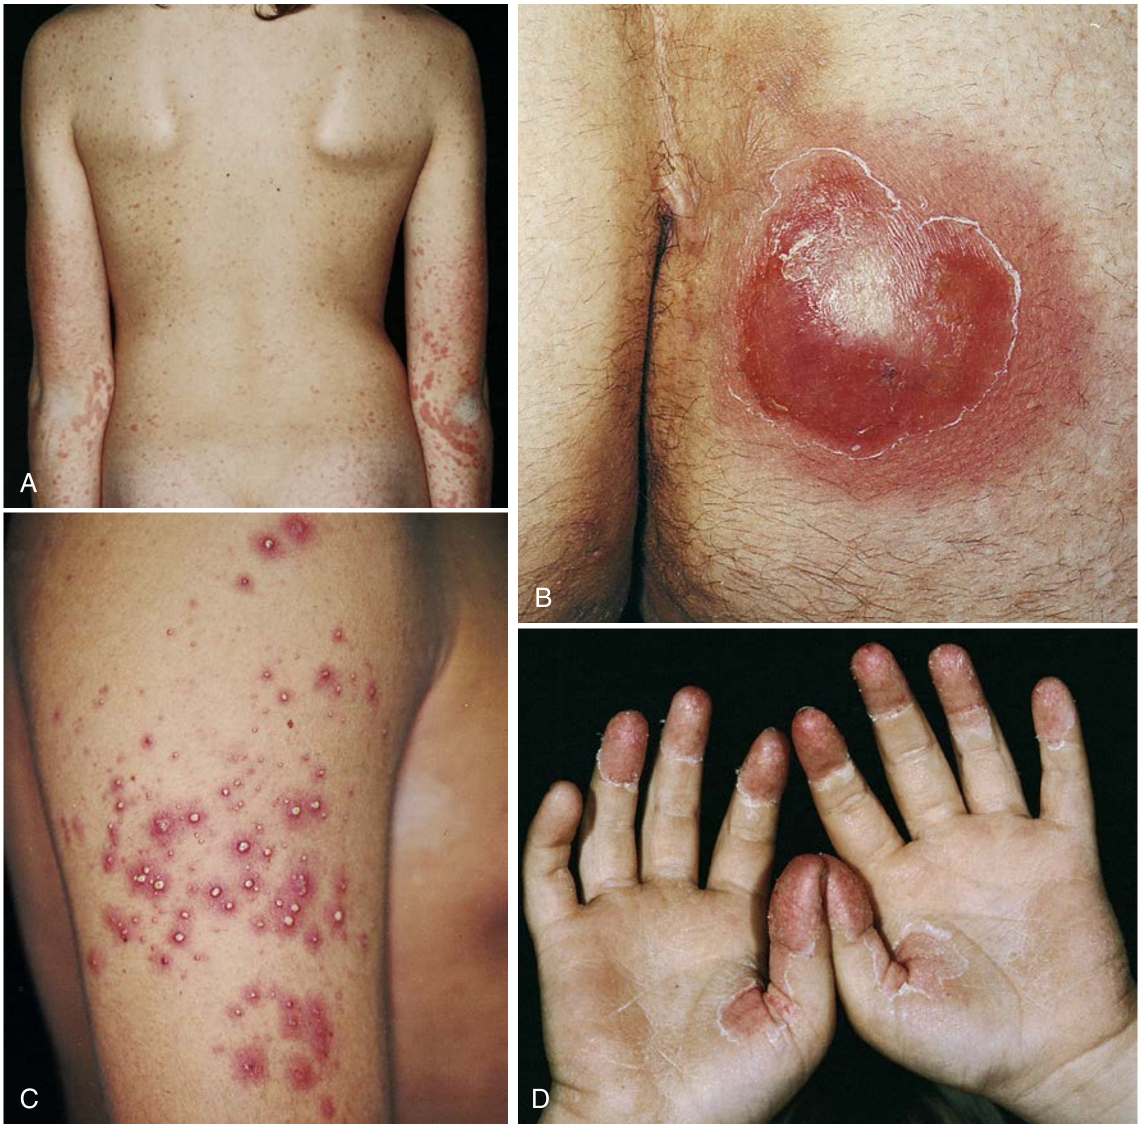
Most infections in the deeper layers of the epidermis and dermis result from the inoculation of microorganisms by traumatic breaks in the skin. These superficial skin infections usually do not require surgical intervention. Table 75.3 summarizes these infections. In most instances, these infections resolve with local care and only occasionally require antimicrobial therapy.

Cutaneous ulcers usually involve a loss of epidermal and part of the dermal tissues. In contrast, **nodules** are inflammatory foci in which the epidermal and dermal layers remain largely intact. Various bacteria and fungi can cause ulcerative or nodular skin lesions after direct traumatic inoculation. Examples of these causative agents include *Bacillus anthracis, Corynebacterium diphtheriae, Mycobacterium marinum, Nocardia* spp., and *Sporothrix schenckii.*

Infections of the Subcutaneous Tissues

Infections of the subcutaneous tissues may manifest as **abscesses, ulcers,** or **boils.** The most common etiologic agent of subcutaneous abscesses in healthy individuals is *S. aureus.* Many subcutaneous abscesses are polymicrobial. To a large degree, the organisms isolated from these abscesses depend on the site of infection. For example, anaerobes are commonly isolated from abscesses of the perineal, inguinal, and buttock area, whereas nonperineal infection is commonly caused by a polymicrobial infection containing facultative organisms.

Progressive synergistic gangrene, or **Meleney ulcer,** is a slowly progressive infection of the subcutaneous tissue that usually begins as an ulcer after trauma or surgery. The infection leads to subcutaneous necrosis and enlargement of a



• **Fig. 75.2** (A) Viral maculopapular rash. (B) Furuncle. (C) Folliculitis caused by *Staphylococcus aureus* showing numerous pustules. (D) Desquamation (shedding or scaling) of the skin resulting from scarlet fever caused by group A streptococci. (A and D, From Habif TB. *Clinical Dermatology: A Color Guide to Diagnosis and Therapy*. 3rd ed. St Louis: Mosby; 1996.)

TABLE 75.2 Infections Involving Hair Follicles

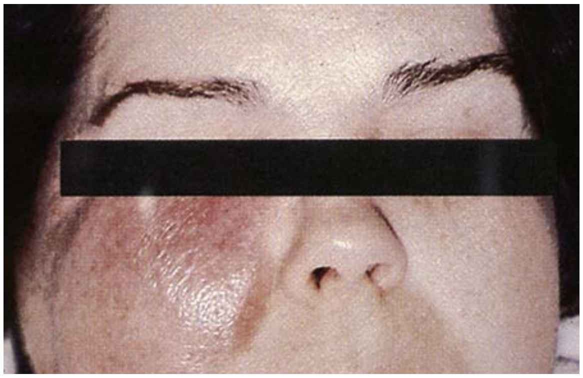
Infection	Skin Manifestations
Folliculitis (minor infection of hair follicles)	Papules or pustules that are pierced by a hair and surrounded with redness
Furuncle (boil)	Abscess that begins as a red nodule in a hair follicle that ultimately becomes painful and full of pus
Carbuncle	Furuncles that coalesce and spread more deeply to the dermis and subcutaneous tissues; they usually have multiple sites, which drain to the skin surface (sinuses)

visible ulcer. This is a true polymicrobial infection in which microaerophilic streptococci grow synergistically with *S. aureus*. The infection may also include other facultative or anaerobic organisms.

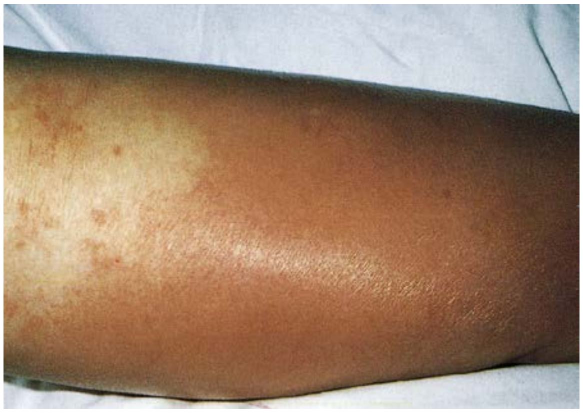
In many instances, infections of the epidermis and dermis extend deeper and become subcutaneous infections and may even reach the fascia or muscle. For example, **erysipelas** (Fig. 75.3) can develop into subcutaneous **cellulitis** and eventually **necrotizing fasciitis.** Similarly, folliculitis can readily develop into a subcutaneous abscess or carbuncle that can extend to the fascia. Cellulitis can also extend to the subcutaneous tissues (Fig. 75.4). Anaerobic cellulitis is associated with the production of large amounts of gas by organisms that may be present in the subcutaneous tissue. This type of infection is most often located in the extremities and is particularly common among patients with

TABLE 75.3 Infections of the Epidermal and Dermal Layers of the Skin

Infection	Key Features of Infection	Etiologies	Other Comments
Erysipelas	Primarily involves the dermis and most superficial parts of the subcutaneous tissue; lesions are painful, red, swollen, and indurated; patients are febrile, and regional lymphadenopathy (swollen glands) is often present; lesion has a marked, well-demarcated, raised border (Fig. 75.3)	Group A streptococci (*Streptococcus pyogenes* [sometimes groups B, C, or G streptococci])	Infants, children, and elderly individuals are most affected; primarily a clinical diagnosis
Erythrasma	Chronic infection of the keratinized layer of the epidermis; lesions are dry, scaly, itchy, and reddish brown	*Corynebacterium minutissimum*—possible cause	Common in diabetics; resembles dermatophyte infection
Erysipeloid	Purplish-red, nonvesiculated skin lesion with an irregular, raised border; the lesions itch and burn; fever and other systemic symptoms are uncommon	*Erysipelothrix rhusiopathiae*	Uncommon; considered an occupational disease
Impetigo	Erythematous (red) lesions that may be bullous (less common) or nonbullous	Nonbullous—group A streptococci *(S. pyogenes)* Bullous—*Staphylococcus aureus*	
Cellulitis	Diffuse, spreading infection involving the deeper layers of the dermis; lesions are ill-defined, flat, painful, red, and swollen; patients have fever, chills, and regional lymphadenopathy (Fig. 75.4)	Commonly: Group A streptococci and other streptococci, *S. aureus* Less common: *Aeromonas* spp., *Vibrio* spp., and *Haemophilus influenzae* (typically affects young children)	Primarily a clinical diagnosis
Dermatophytoses	Superficial fungal infections of the skin and its appendages (i.e., ringworm, athlete's foot, jock itch, and infections of nails and hair)	*Epidermophyton, Microsporum,* and *Trichophyton* spp.	
Hidradenitis	Chronic infection of obstructed apocrine (sweat) glands in the axillar, genital, or perianal areas with intermittent discharge of often foul-smelling pus	*S. aureus, Streptococcus anginosus* group, anaerobic streptococci, and *Bacteroides* spp.	
Infected pilonidal tuft cyst or hairs	Pain and swelling; redness	Anaerobes, including *Bacteroides fragilis* group, *Prevotella, Fusobacterium,* anaerobic gram-positive cocci, and *Clostridium* spp.	



• **Fig. 75.3** Erysipelas caused by group A streptococci.



• **Fig. 75.4** Cellulitis. (From Farrar WE, Wood MJ, Innes JA, et al. *Infectious Diseases: Text and Color Atlas.* 2nd ed. London: Mosby-Wolfe; 1992.)

diabetes. The infection may involve the neck, abdominal wall, perineum, connective tissue, or other areas. Anaerobic cellulitis may also occur as a postoperative condition. The onset and spread of the lesion are usually slow, and patients may not immediately show obvious systemic effects. The causative agents in deep tissue infections are almost always a mixture of aerobic, facultative, and anaerobic organisms. Common aerobic, facultative organisms include *Escherichia coli,* alpha-hemolytic and nonhemolytic streptococci, and *S. aureus*. However, group A streptococci and other members of the Enterobacterales may be encountered as well. The anaerobes are typically found in greater numbers and in more varieties and include *Peptostreptococcus* spp., *Bacillus fragilis* group strains, *Prevotella* spp., *Porphyromonas* spp., other anaerobic gram-negative bacilli, and clostridia. Bacteremia is not usually present.

Infections of the Muscle Fascia and Muscles

There are several uncommon, yet serious or potentially serious, forms of deep and often extensive soft tissue and skin infections.

Necrotizing Fasciitis

Necrotizing fasciitis is a serious infection that is relatively uncommon. The basic pathology involves infection of the fascia overlying the muscles, often with involvement of the overlying soft tissue. At the fascial level, no barrier exists to prevent the spread of infection, so fasciitis may extend widely and rapidly to involve large areas of the body in a short amount of time. There are three distinct types of necrotizing fasciitis based on the bacteriological agents involved in the infection. Type I is polymicrobial and typically involves *Bacteroides* or *Peptostreptococcus* in combination with one or more facultative organism, such as group A streptococci or Enterobacterales. Type II is generally a monomicrobic infection with group A streptococci but may be associated with another species, often *S. aureus*. Type III is a result of infection with marine gram-negative pathogens, such as *Aeromonas hydrophilia* or *Vibrio* spp. Necrotizing fasciitis is most often acute and can affect any area of the body.

Progressive Bacterial Synergistic Gangrene

Progressive bacterial synergistic gangrene is usually a chronic necrotic condition of the skin most often encountered as a postoperative complication, particularly after abdominal or thoracic surgery or other medical procedures and devices, such as a colostomy (opening that connects the colon to the abdominal wall). The lesions may be extensive and, with involvement of the abdominal wall, may lead to **evisceration** (extrusion of the internal organs). As the name implies, this is a synergistic polymicrobial infection with microaerophilic streptococci and *S. aureus.* Other organisms may also be present, including anaerobic streptococci, *Proteus* spp., other gram-negative bacilli, or other facultative and anaerobic bacteria. This type of infection is uncommon. Cultures should be taken from the advancing outer edge of the lesion (not the central portion of the wound). This prevents missing cultivation of microaerophilic streptococci that may be involved in the infection.

Myositis

Myositis (inflammation of muscle) can be caused by a variety of organisms. The nature of the pathologic process is variable, sometimes involving extensive necrosis of muscle or focal collections of suppuration (pus) in muscle (**pyomyositis**). This may occur because of a penetrating wound, vascular insufficiency in an extremity, or another contiguous infection. The most common cause of acute bacterial myositis from hematogenous spread is *S. aureus.* Categories of bacterial myositis include pyomyositis, psoas abscess (pus in the iliopsoas muscle compartment), *S. aureus* myositis, group A streptococcal necrotizing myositis, group B streptococcal myositis, clostridial gas gangrene, and nonclostridial myositis. Serious vascular problems resulting from loss of blood supply may lead to death of muscle tissue, leading to a secondary infection (vascular gangrene). Organisms that cause myositis or other muscle pathology are listed in Box 75.2.

Wound Infections

Besides skin and soft tissue infections, wound infections occur primarily from breaks in the skin because of complications associated with surgery, trauma, and bites, or from diseases that interrupt the mucosal or skin surface.

• BOX 75.2 Organisms Producing Myositis or Other Muscle Pathology

Clostridium perfringens
Clostridium novyi
Clostridium septicum
Clostridium histolyticum
Clostridium sordellii
Clostridium sporogenes
Paraclostridium bifermentans (previously *Clostridium*)
Bacillus spp.
Aeromonas spp.
Peptostreptococcus spp.
Microaerobic streptococci
Bacteroides spp.
Enterobacterales
Staphylococcus aureus
Group A streptococci *(Streptococcus pyogenes)*
Pseudomonas spp.
Vibrio vulnificus
Mycobacterium tuberculosis
Salmonella enterica serotype Typhi
Legionella spp.
Rickettsia spp.
Viruses
Trichinella spp.
Taenia solium
Toxoplasma gondii

Microbial biofilms have also increased the length and chronicity of wound infections.

Postoperative Infections

Surgical site infections are among the most common health care–associated infections. Sources of surgical wound infections can include the patient's normal microbiota or organisms present in the hospital environment. These organisms are introduced to the patient by medical procedures or underlying disease or trauma (e.g., burns). The nature of the infecting organism depends on the patient's underlying condition and the location of the medical treatment or procedure. The most common organism involved in postoperative infections is *S. aureus.* Surgical procedures in the colorectal or other lower gastrointestinal areas have the highest incidence of postoperative infections because of the presence of intestinal bacteria. These infections are most likely to be caused by enteric gram-negative bacteria, anaerobes, and enterococci. Principal pathogens are listed in Box 75.3.

Bites

Bite wounds can be the result of human teeth, as well as a large variety of domestic or wild animals. The infectious agents associated with the bite may come from the environment, the victim's normal skin microbiota, and the oral flora of the biter. This makes the variety of potential infectious agents quite diverse. Human bite (Fig. 75.5) infections can be attributed to occlusion bites or closed-fist injuries. Not surprisingly, the most commonly isolated organisms are normal oral microbiota. Most frequently isolated are viridans streptococci (particularly *Streptococcus anginosus*), *S. aureus,* and *Eikenella corrodens.* Common anaerobes isolated include *Prevotella*, *Fusobacterium, Veillonella,* and *Peptostreptococcus* species. These infections are usually polymicrobial and contain both aerobic and anaerobic organisms.

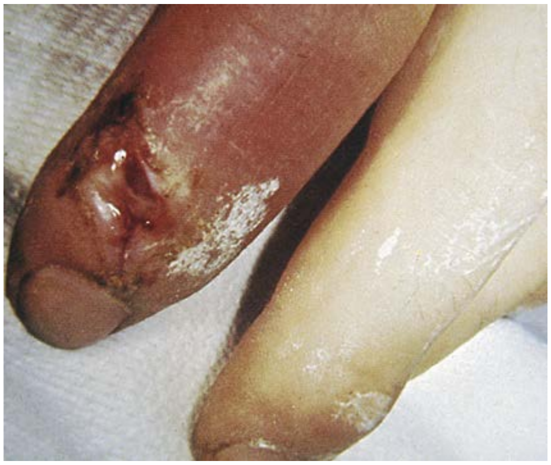
• BOX 75.3 Organisms Encountered in Postoperative Wound Infections

Staphylococcus aureus
Coagulase-negative staphylococci
Streptococcus pyogenes
Streptococcus anginosus group streptococci *(Streptococcus anginosus, Streptococcus constellatus, Streptococcus intermedius)*
Microaerophilic streptococci
Enterococci
Proteus, Morganella, and *Providencia* spp.
Other Enterobacterales
Escherichia coli
Pseudomonas spp.
Candida spp.
Bacteroides spp.
Prevotella and *Porphyromonas* spp.
Fusobacterium spp.
Clostridium spp.
Peptostreptococcus spp.
Non–spore-forming, anaerobic, gram-positive bacilli

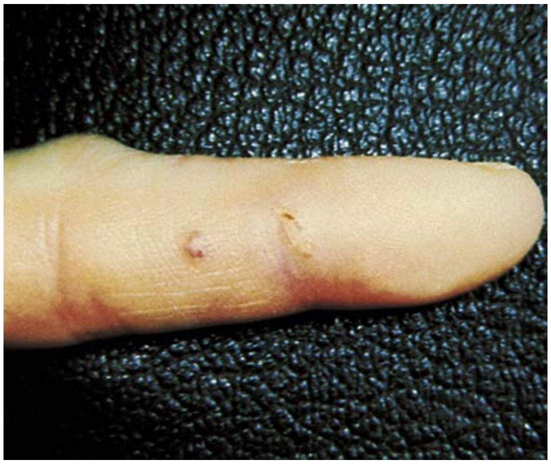
Animal bites account for approximately 1% of all emergency room visits in the United States. The most common animal bites are from domestic cats and dogs. Bites from these animals (Fig. 75.6) usually are infected with organisms commonly found in the animal's oral and nasal fluids. The most commonly isolated aerobes are *Pasteurella, Streptococcus, Neisseria*, and *Staphylococcus* species. The most commonly isolated anaerobes are *Fusobacterium, Bacteroides,* and *Porphyromonas* species. Similar to human bites, animal bite wound infections are usually polymicrobial and include aerobes and anaerobes. Other far less common animal bites may also become infected. Rat bite infections are usually caused by *Streptobacillus moniliformis.* Snakebites may become infected with *A. hydrophilia.*

Burns

Burns are a significant cause of mortality due to hospital-associated infections; 42% to 65% of deaths in burn patients are associated with infection. Infected burn wounds may be associated with many organisms, causing significant mortality, and may interfere with the success of skin grafts. Bacteria cause 70% of burn wound infections, 20% to 25% are caused



• Fig. 75.5 Human bite infection.



• Fig. 75.6 Animal bite infection caused by *Pasteurella* spp.

by fungi, and anaerobic organisms and viruses cause 5% to 10%. Burn wound infections can commonly be identified as four types: **impetigo;** surgical infections; cellulitis; bacteremia and invasive, systemic infections. Factors that contribute to the development of infection include loss of the skin barrier, coagulated proteins and other microbial nutrients, loss of vascularity of the wound, dehydration of surrounding tissue, and the inflammatory response of the patient's immune system. Gram-positive organs tend to be isolated from early infections, whereas the incidence of infection with gram-negative organisms increases with the length of hospitalization. The organisms isolated most often from burns include *S. aureus, P. aeruginosa,* enterococci, *Enterobacter* spp., and *E. coli.* Other organisms, such as fungi (e.g., *Candida* spp., *Aspergillus niger*, *Fusarium* spp., and *Mucor* spp.) and viruses may also be involved in invasive burn infections. The risk of infections with multidrug-resistant organisms also increases with the length of stay for burn patients. These organisms include *P. aeruginosa, Acinetobacter baumannii, Stenotrophomonas maltophilia,* and *S. aureus.*

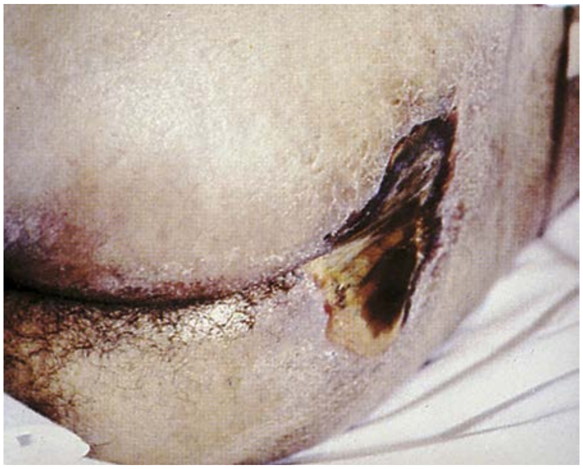
Special Circumstances Regarding Skin and Soft Tissue Infections

In addition to the infections previously discussed, other circumstances can cause skin and underlying soft tissue to become infected. Some of these infections are associated with an immunocompromised host; others are manifestations of systemic infection.

Infections Related to Vascular and Neurologic Problems

Frequently, a patient with infections associated with vascular or neurologic problems has diabetes mellitus. These patients have a high risk of developing infections, especially in their lower extremities. The excess glucose present in their blood can result in impaired microvascular circulation and peripheral motor neuropathy, leading to an increased risk of infection. Any skin-damaging injury or surgery greatly increases that risk. In addition, because of the complications associated with impaired circulation and neuropathy, the infected tissue of a diabetic patient does not heal as rapidly as that of a healthy individual. An estimated 25% of adults with diabetes will develop a foot infection, and the risk increases with age. Foot infections can lead to amputations and greatly increased mortality. Periodically, an acute cellulitis and lymphangitis may be associated with chronic, low-grade infection, thereby making control of the patient's diabetes difficult. Peripheral vascular disease unrelated to diabetes may also predispose a patient to skin and soft tissue infections, but usually these infections are easier to manage because there is no associated neuropathy.

Foot infections in diabetic patients can accelerate dramatically, producing devastating consequences without proper treatment. Therefore, appropriate techniques used to obtain a microbiologic sample are critical. Culture of aspirated fluid or pus, not surface swabbing, is more likely to yield a causative agent—particularly if taken from a deep pocket within the wound. In addition, culture of debrided infected tissue improves the diagnosis of these infections. The most common bacteria isolated from mild to moderate diabetic foot infections include *S. aureus,* group B streptococci, members of the Enterobacterales, and anaerobes. More severe infections are usually polymicrobial. Extension of the infection into the underlying bone produces a difficult-to-manage osteomyelitis. Definitive diagnosis of this infection requires a specimen of bone obtained during open or percutaneous biopsy.



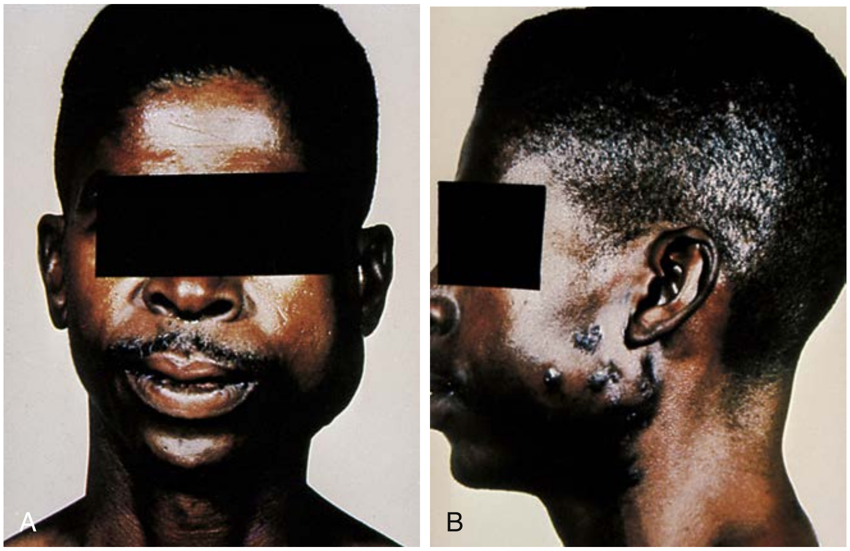
• **Fig. 75.7** Sacral decubitus ulcer.

Venous insufficiency may also predispose an individual to infection, again primarily in the lower extremities (often in the calf or lower leg rather than the foot). Infections related to poor blood supply often involve *S. aureus* and group A streptococci. Those with open ulcers may become colonized with Enterobacterales and *P. aeruginosa.* Anaerobes are also frequently involved in these infections, as a result of the blood supply creating anaerobic conditions. Anaerobes that may be involved include *Bacteroides fragilis* group, *Prevotella, Porphyromonas, Peptostreptococcus* and, less commonly, *Clostridium* species.

Another common type of infection in this general category, especially in the elderly or chronically ill, bedridden patient, is infected **decubitus ulcer** (pressure sore; Fig. 75.7). Anaerobic conditions are present in the lesions as a result of tissue necrosis. Most of these lesions are located near the anus or on the lower extremities. Because these patients are relatively helpless and have limited mobility, the ulcers may become contaminated with gastrointestinal bacteria, leading to chronic infection. These conditions contribute to further death of tissue and extension of the decubitus ulcer. Bacteremia is a possible complication; *B. fragilis* group is often involved, as are clostridia and other enteric bacteria. Health care–associated pathogens, such as *S. aureus* and *P. aeruginosa,* may also be recovered.

Sinus Tracts and Fistulas

Sometimes, a deep-seated infection will develop a channel, called a **sinus tract,** to the skin surface. The sinus tract will



• **Fig. 75.8** Actinomycosis. (A) Note “lumpy jaw.” (B) Side view. Note sinuses in skin of face and neck.

drain fluid and pus onto the skin. The infections involved are often chronic and may include osteomyelitis. The organisms commonly involved in sinus tract formation with an underlying osteomyelitis include *S. aureus,* various members of the Enterobacterales, *P. aeruginosa,* anaerobic gram-negative bacilli, and anaerobic gram-positive cocci. In the case of actinomycosis (Fig. 75.8), with or without bone involvement, the organisms involved include *Actinomyces* spp., *Aggregatibacter actinomycetemcomitans, Propionibacterium propionicum, Prevotella* or *Porphyromonas* species, and other non–spore-forming anaerobes. Chronic draining sinuses may also be found in patients with tuberculosis and atypical mycobacterial infection, *Nocardia* infection, and infections associated with implanted foreign bodies. Curetting or biopsy specimens from the debrided, cleansed sinus should be used for culture.

Abnormal channels connecting epithelial surfaces, either between two internal organs or between an organ and the skin epithelium, are known as **fistulas.** Infections associated with fistulas often pose insurmountable problems in terms of collecting a meaningful specimen because the organ involved may contain indigenous microbiota. Examples include perirectal fistulas from the small bowel to the skin associated with Crohn disease or chronic intraabdominal infection. When the bowel is involved, cultures for specific organisms, such as mycobacteria or *Actinomyces,* are useful. An attempt should always be made to rule out specific associated underlying causes, such as tuberculosis, actinomycosis, and malignancy. A biopsy should be performed in these situations.

Systemic Infections and Skin Manifestations

Cutaneous manifestations of systemic infections, such as bacteremia or endocarditis, may be important clues for the clinician. These represent an opportunity for direct detection or culture for the presence of an organism. For example, a scraping of **petechiae** (tiny red hemorrhagic spots in the skin) from patients with meningococcemia may demonstrate the presence of gram-negative diplococci. In other patients, the skin lesion may represent a metastatic infection. In *Vibrio vulnificus* sepsis, dramatic-appearing cutaneous ulcers with **necrotizing vasculitis** or **bullae** may be seen. In some patients, skin lesions may represent a noninfectious complication of a local or systemic infection, such as scarlet fever or toxic shock syndrome. Various organisms involved in systemic infections capable of producing cutaneous lesions are listed in Box 75.4.

Laboratory Diagnostic Procedures

Infections of the Epidermis and Dermis

For many of the infections of the epidermis and dermis, such as impetigo, folliculitis, cellulitis, and erysipelas, diagnosis is generally based on clinical observations. Table 75.3 provides the key features and etiologic agents of these infections.

Erysipeloid

In **erysipeloid,** usually the Gram stain or culture of superficial wound drainage is negative. However, culture of a full-thickness skin biopsy taken at the margin of the lesion can confirm the clinical diagnosis.

Superficial Mycoses and Erythrasma

If a dermatophyte infection is suspected, the lesion is cleaned, and scrapings are obtained from the active border of the lesion. These scrapings should be treated with 10% potassium hydroxide and examined for the presence of hyphae. The specimen may also be cultured if necessary (Chapter 59). A Woods lamp examination of the skin lesions for tinea versicolor may show golden-yellow fluorescence.

Erythrasma, which is caused by infection with *Corynebacterium minutissimum,* can be diagnosed by making smears from the lesion revealing gram-positive pleomorphic

• BOX 75.4 Organisms Involved in Systemic Infection With Cutaneous Lesions

Viridans streptococci
Staphylococcus aureus
Enterococci
Group A and other beta-hemolytic streptococci
Neisseria gonorrhoeae
Neisseria meningitidis
Haemophilus influenzae
Pseudomonas aeruginosa
Pseudomonas spp.
Listeria monocytogenes
Vibrio vulnificus
Salmonella enterica serotype Typhi
Mycobacterium tuberculosis
Mycobacterium leprae
Treponema pallidum
Leptospira spp.
Streptobacillus moniliformis
Bartonella bacilliformis
Bartonella henselae
Rickettsia spp.
Candida spp.
Cryptococcus spp.
Blastomyces dermatitidis
Coccidioides immitis
Histoplasma capsulatum

bacilli. If necessary, skin scrapings may be cultured in media containing serum. A Woods lamp examination of the skin lesions may reveal a coral red fluorescence resulting from the production of porphyrin by *C. minutissimum.*

Erysipelas and Cellulitis

As previously mentioned, diagnosis of erysipelas and cellulitis can generally be made based on clinical observation. Swab specimens from bullae, pustules, or ulcers may be cultured. Culturing of needle aspiration or punch biopsy specimens is not recommended and rarely informative. Blood cultures are also typically negative.

Vesicles and Bullae

These fluid-filled lesions characteristically involve specific organisms (Table 75.1). Material in a blisterlike lesion may vary from **serous** (resembling serum) **fluid** to **serosanguineous** (composed of serum and blood) **fluid** or **hemorrhagic** (bloody) **fluid.** Large bullae may permit withdrawal of fluid by needle and syringe aspiration. Specimens from tiny vesicles may need to be collected with a swab. The clinician can usually anticipate whether the lesion is viral or bacterial and may even suspect an organism. Specimens should be submitted for viral or bacterial culture based on the clinical presentation.

Bullous lesions are often associated with sepsis, requiring the collection of blood for nucleic acid testing or cultures. Gas gangrene caused by *Clostridium perfringens* and other clostridia is characterized by bronzed skin with bullous lesions. Gram stain of the fluid from the lesions typically reveals gram-positive bacilli.

Infections of the Subcutaneous Tissue

Proper collection and transport of specimens are important factors in the laboratory diagnosis of all infections. Specimen collection for the diagnosis of subcutaneous tissue infection is particularly difficult, because many of these lesions are open and readily colonized by nosocomial pathogens that may not be involved in the systemic underlying infection. The most reliable specimens for determining the etiology of ulcers and nodules are those obtained from the base of the ulcer or nodule after removal of overlying debris, or by surgical biopsy of deep tissues, avoiding contact with the superficial layers of the lesion. A Gram stain of the specimen should be performed, and material aerobically cultured on blood and MacConkey agar. If fungi, *Nocardia* spp., or mycobacterial infection is suspected, appropriate fungal media or mycobacterial media should be used. These culture methods are addressed in greater detail in Chapters 42 and 59, respectively.

Similar challenges exist in collecting material for culture from sinus tracts. The material should be obtained from the deepest portion of the sinus tract. If systemic symptoms, such as fever, are present, blood cultures should also be collected. A Gram stain should be routinely performed. Cultures should be inoculated to recover both facultative and anaerobic bacteria in the same manner as for surgical wounds. Nucleic acid–based assays may be used to directly identify organisms, such as *S. aureus,* in wound infections. In addition, when deep tissue or bone infections are suspected and yield negative culture results, molecular assays may aid in the identification of the infectious agent.

Infections of the Muscle Fascia and Muscles

Blood cultures should always be collected from patients with significant **myonecrosis.** Transport of material (tissue is recommended, followed by purulent material, and then a swab) should be under anaerobic conditions. Gram stains should be routinely performed. Cultures should be inoculated to recover both facultative and anaerobic bacteria in the same manner as for surgical wounds.

Wound Infections

Postoperative

Because anaerobic bacteria are involved in many of these infections, specimen collection should be completed carefully to avoid indigenous microbiota. Specimen transport in anaerobic conditions is essential. Unusual organisms associated with postsurgical wound infections, such as *Mycoplasma hominis, Mycobacterium chelonae, Mycobacterium fortuitum,* fungi, and even *Legionella* spp., should not be overlooked. A Gram-stained smear of material submitted for culture should be examined. Exudates from superficial wounds should routinely be inoculated to blood, MacConkey, and Colistin-nalidixic acid (CNA) agars, as well as an enrichment broth. Material from deep wounds should be inoculated onto media for both anaerobic and aerobic cultures. More detailed information regarding the processing of specimens for anaerobic cultures is presented in Chapters 40 and 41.

Bites

Bite wound infections usually involve relatively small lesions and minimal exudate. A swab specimen for aerobic culture and one in anaerobic transport media should be collected. Surrounding skin should be thoroughly disinfected before the specimen is obtained. The best material for culture is purulent exudate aspirated from the depth of the wound or samples obtained during surgery involving incision and drainage or **debridement** (removal of all dead and necrotic tissue). Gram-stained smears should be prepared and examined. For aerobic cultures, a minimum of blood, MacConkey, and chocolate agar should be inoculated.

Burns

For many burn patients, diagnosis of infection is based on clinical symptoms, signs, and examination of the burn wound. When possible, cultures should be performed on any purulent wound exudates, and blood cultures should also be collected. Surface specimens should be collected with a moistened sterile swab using a minimal amount of pressure. Sometimes a quantitative or semiquantitative culture (Evolve Procedure 75.1) of a tissue biopsy specimen is used for infection surveillance, or to identify the most prevalent organism in a polymicrobial infection. This type of culture is reported in colony-forming units (CFUs) per gram of tissue, with a result of 10^5 CFUs/g or more indicative of a potentially serious infection.

Visit the Evolve site for a complete list of procedures, review questions, and case studies.

PROCEDURE 75.1

Semiquantitative Bacteriologic Culture of Tissue

Principle

The degree or extent of bacterial wound contamination is directly related to the risk of wound sepsis. Because of this relationship, physicians use the results of a quantitative culture (the number of colony-forming units [CFUs] per gram of the eschar biopsy) in their management of severely burned patients.

Method

1. Cut a piece of tissue, measuring several cubic millimeters, aseptically onto a small, preweighed, sterile urine cup.
2. Determine the weight of the tissue by subtracting the weight of the aluminum foil from the total weight.
3. Place the specimen and 2 mL of sterile nutrient broth in a sterile tissue grinder; macerate the specimen.
4. Inoculate 0.1 mL of sample to a blood agar plate, in duplicate, and an anaerobic blood agar plate (if indicated), in duplicate. In addition, inoculate 0.01 mL of sample using a calibrated loop to a blood agar plate, in duplicate. Spread the inoculum on the plates with a sterile glass spreading rod or a loop.
5. Incubate plates in 5% to 10% carbon dioxide overnight and count the colonies of bacteria on the plates that contain 30 to 300 CFUs. If more than 300 colonies are obtained on both plated dilutions, the factor 300 is used as N for calculations and the result is considered greater than the value.
6. Calculate the number of CFUs per gram of tissue with the following formula:
   Number of CFUs counted × Reciprocal of volume of homogenate inoculated (10^{-1} or 10^{-2}) × 2 (volume of diluent used for tissue homogenization) ÷ weight of tissue

   For example, for a tissue that weighed 0.002 g, 68 CFUs were observed on the plate that received the 10^{-2} dilution of suspension:

$$\frac{68 \times 10^{2} \times 2}{0.002} = \frac{136 \times 10^{2}}{2 \times 10^{-3}} = 6.8 \times 10^{6}\ \mathrm{CFU/g}$$

Modified from a method published by Buchanan K, Heimbach DM, Minshew BH, et al. Comparison of quantitative and semiquantitative culture techniques for burn biopsy. *J Clin Microbiol.* 1986;23:258.

CASE STUDY 75.1

A 59-year-old female presented with swelling and pain in an injured left hand and enlarged lymph nodes in the axial region of her left arm. Her hand was injured when she stopped on her way home from work to rescue a small kitten that had wandered into the road. When she attempted to pick up the frightened kitten, it scratched her left hand. A specimen for culture was obtained by aspiration from the wound. A Gram stain showed small, gram-negative bacilli. The culture showed no growth on blood and MacConkey agar and sparse growth on chocolate agar.

Questions

1. The isolate was oxidase negative and catalase negative. Given this information, what is the suspected causative bacterium?
2. What would be the expected results if urease and nitrate reductase tests were performed?
3. What serology tests could be performed to identify this bacterium?

CASE STUDY 75.2

A 45-year-old female presented to the clinic with a complaint of a painful skin lesion on her back. This developed spontaneously 24 hours earlier. One month prior, she had a similar lesion on her thigh that was treated successfully with a sulfa drug but was not cultured.

Evaluation revealed no fever, and she appeared to be in mild distress. Laboratory results revealed the following: CBC: WBC 12K, HGB 13K, HCT 39, PLTS 325K.

The abscess was drained. A Gram stain of the thick, cream-colored purulent drainage revealed gram-positive cocci in clusters. The lesion was thoroughly irrigated, and the patient was prescribed oral sulfa antimicrobial therapy. The lesion resolved, and the woman returned 2 months later with another lesion.

Questions

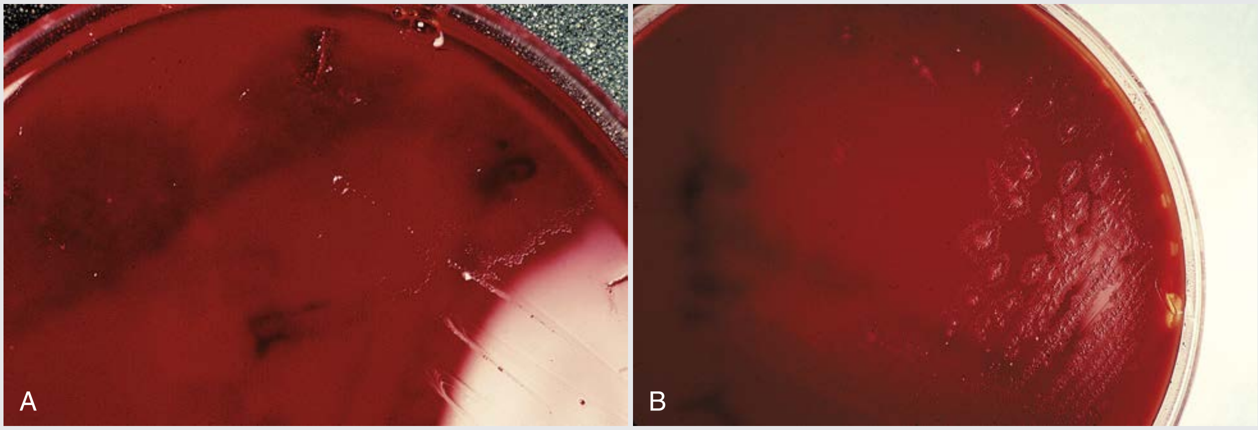
1. Given the patient's clinical presentation and previous complaint of a lesion on her thigh, what would be the suspected infecting organism?
2. Because of the recurring nature of her infection, how would the physician determine whether the patient was colonized with the organism?

CASE STUDY 75.3

A 50-year-old male presented with extreme pain in his left thigh. He had an elevated measurement of creatine phosphokinase (CPK), an enzyme found predominantly in the heart, brain, and skeletal muscle. When the CPK is elevated, it usually indicates injury or stress to one or more of these areas. His heart muscle CPK fraction was normal. A biopsy specimen was collected by fine-needle aspiration. Gram stain showed gram-positive bacilli with subterminal spores. The aerobic culture was sterile, but the anaerobic culture grew a pure culture of bacteria with the same Gram stain morphology as seen in the direct smear. The colony had irregular edges like a medusa head; a film of growth swarmed over the entire plate in 24 hours (Fig. 75.9).

Questions

1. The isolate was indole-negative. Given this information, what is the genus and species of these bacteria?
2. What does the positive test for CPK indicate in this patient?
3. Infections with *Clostridium septicum* are an indication of what underlying diseases?



• **Fig. 75.9** Demonstration of the swarming film of growth of *Clostridium septicum* at 24 hours (A) and *Clostridium sporogenes* (B).

Chapter Review

1. Primary functions of the skin include all the following *except:*
- **a.** Assists in maintaining body temperature
- **b.** Hydrates the body by absorbing fluid
- **c.** Provides a protective outer barrier
- **d.** Acts as a sensory organ
- **e.** Acts as a site for chemical synthesis

2. Which chemical properties of the skin assist in the prevention of infection?
- **a.** pH, NaCl, oil
- **b.** NaCl, pH, sebum, bacteria
- **c.** pH, bacteria
- **d.** Sebum, NaCl

3. What factor enhances the development of an infection after a burn?
- **a.** Minimal loss of skin
- **b.** Dehydration and loss of tissue
- **c.** Increased vascularity
- **d.** Lack of inflammation

4. A patient presented to the physician with a wound to the right index finger. The patient indicated his pet rat had bit him. Upon cultivation of the wound, a gram-positive catalase-positive rod was isolated. What is the most likely organism?
- **a.** *S. aureus*
- **b.** *P. multocida*
- **c.** *S. moniliformis*
- **d.** *C. perfringens*

5. The technologist received a swab specimen from a perirectal fistula. The specimen appears contaminated with feces. What should the technologist do?
- **a.** Reject the specimen
- **b.** Culture the specimen
- **c.** Culture the specimen for both aerobic and anaerobic organisms
- **d.** Culture the specimen for both aerobic and anaerobic organisms and notify the physician of possible specimen contamination

6. Matching: *Match each term with the correct description.*

_____ cellulitis

s. circumscribed purulent lesion
t. flat discoloration
u. outer squamous epithelium
v. subcutaneous

7. Short Answer
- **(1)** What organisms are commonly associated with folliculitis?
- **(2)** In what ways are infections in the subcutaneous tissues usually manifested?
- **(3)** What are the various ways that wound infections can occur?
- **(4)** Why are patients with diabetes mellitus prone to foot infections?

76

Normally Sterile Body Fluids, Bone and Bone Marrow, and Solid Tissues

OBJECTIVES

1. Describe the five main cavities of the human body; also name the membranes associated with these cavities and state the function of these membranes.
2. Define each of the following body cavity fluids and explain the diagnostic culture methods for each: pleural fluid, pericardial fluid, peritoneal fluid, joint fluid, and dialysis fluid.
3. Define parietal and visceral pleura.
4. Define cellulitis; name the etiologic agents of this illness and explain the associated risk factors for the development of disease.
5. Define pleural effusion; explain the difference between exudative pleural effusion and transudative pleural effusion.
6. Explain when a pleural effusion becomes an empyema and what medical condition contributes to the development of an empyema?
7. Define pericarditis and myocarditis; explain the physical conditions that may contribute to the accumulation of pericardial fluid.
8. Define peritonitis; differentiate between primary and secondary peritonitis.
9. Name the etiologic agents most commonly isolated from primary peritonitis cases in children, adults, sexually active females, and immunocompromised patients.
10. Define osteomyelitis; explain how this infection is transmitted, the diagnostic method, and the organisms most commonly responsible for this type of infection.
11. Explain the process for culturing organisms from the following specimens: bone, tissue, and bone marrow.
12. Correlate patient signs and symptoms with laboratory results to identify the etiologic agent associated with the body fluid, bone and bone marrow, and other solid tissue infection.

The human body is divided into five main body cavities: cranial, spinal, thoracic, abdominal, and pelvic. Each cavity is lined with membranes, and within the body wall and these membranes, or **between** the membranes and organs, are small spaces filled with minute amounts of fluid. The purpose of this fluid is to bathe the organs and membranes, reducing friction between organs.

Bacteria, fungi, viruses, or parasites can invade any body tissue or sterile body fluid site. Although from different areas of the body, all specimens discussed in this chapter are considered normally sterile. Therefore, even one colony of a potentially pathogenic microorganism may be significant. (Refer to Table 5.1 for a quick guide regarding collection, transport, and processing of specimens from sterile body sites.)

Specimens From Sterile Body Sites

Fluids

In response to infection, fluid may accumulate in any body cavity. Infected solid tissue often presents as cellulitis or with abscess formation. Areas of the body from which fluids are typically sent for microbiologic studies (in addition to blood and cerebrospinal fluid [Chapters 67 and 70]) are listed in Table 76.1. In general, peritoneal, pleural, and pericardial fluids may be cultured in aerobic and anaerobic blood culture bottles. This method should not be used if a polymicrobial infection is suspected, as some organisms can overgrow fastidious or other slow-growing organisms resulting in incomplete identification of the pathogens.

Pleural Fluid

Lining the entire thoracic cavity (Chapter 68) of the body is a serous membrane called the **parietal pleura.** Covering the outer surface of the lung is another membrane called the **visceral pleura** (Fig. 76.1). Within the pleural space between the lung and chest wall is a small amount of fluid called **pleural fluid** that lubricates the surfaces of the pleura (the membranes surrounding the lungs and lining of the chest cavity). Normally, equilibrium exists among the pleural membranes, but in certain disease states, such as cardiac, hepatic, or renal disease, excess amounts of this fluid can be produced and accumulates in the pleural space; this is known as a **pleural effusion.** Pleural effusions can either be exudative or transudative. **Exudative pleural effusions** are caused by inflammation, infection, and cancer, whereas **transudative effusions** result from systemic changes, such as congestive heart failure.

Normal pleural fluid contains few or no cells and has a consistency similar to serum, but with a lower protein count. Pleural fluid containing numerous white blood cells is indicative of infection. Pleural fluid specimens are collected by **thoracentesis,** a procedure in which a needle is inserted through the chest wall into the pleural space and the excess fluid aspirated. This fluid is then submitted to the laboratory as thoracentesis fluid, pleural fluid, or empyema fluid. The fluid, or effusion, can then be analyzed for cell count, total protein, glucose, lactate dehydrogenase, amylase, cytology, nucleic acid testing, and culture. The total protein and glucose results determine whether the effusion is transudate or exudate. The patient's serum or plasma glucose level is needed to compare with the results indicated in the body fluid. Several characteristics can be used to determine whether a fluid is a transudate or exudate (Table 76.2).

TABLE 76.1 **Microbiology Laboratory Body Fluid Collection Sites**

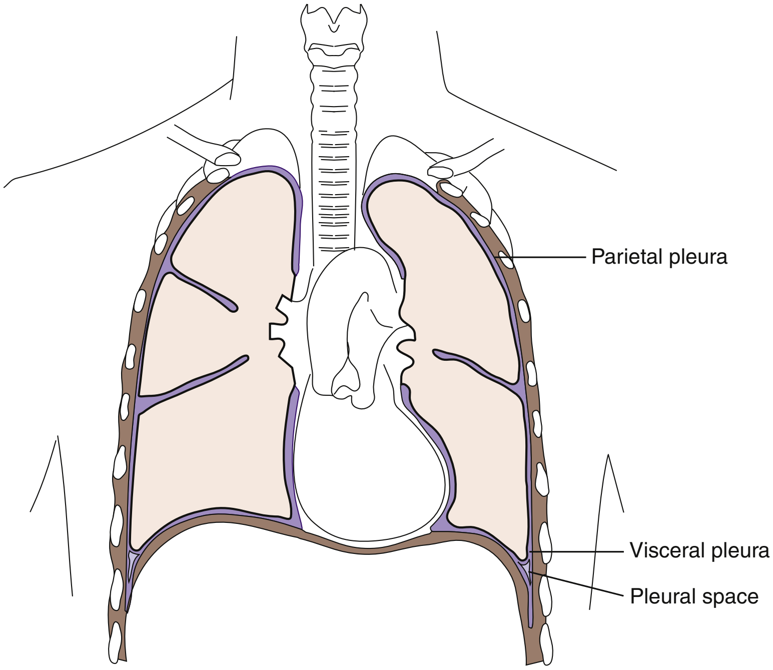
Body Area	Fluid Name(s)
Thorax	Thoracentesis or pleural or empyema fluid
Abdominal cavity	Paracentesis or ascitic or peritoneal fluid
Joint	Synovial fluid
Pericardium	Pericardial fluid

When effusions are extremely purulent (i.e., full of pus), the effusion is referred to as an **empyema.** Empyema often arises as a complication of pneumonia, but other infections near the lung (e.g., subdiaphragmatic infection) may seed

TABLE 76.2 **Pleural Fluid Effusion Characteristics**

	Transudate	Exudate
Appearance	Clear	Cloudy
Specific gravity	<1.015	>1.015
Total protein	<3.0 mg/dL	>3.0 mg/dL
LD fluid/serum ratio	<0.6	>0.6
Cholesterol	<60 mg/dL	>60 mg/dL
Cholesterol fluid/ serum ratio	<0.3	>0.3
Bilirubin fluid/ serum ratio	<0.6	>0.6
Total protein fluid/ serum ratio	<0.5	>0.6
White blood cells	<1000/µL (all white blood cell types, all <50%)	>1000/µL
Red blood cells	<10,000/µL = because of traumatic tap	>100,000/µL
Clotting	Will not clot	May clot

Modified from Strasinger SK, Di Lorenzo MS. *Urinalysis and Body Fluids.* 5th ed. Philadelphia: F.A. Davis; 2008.



• **Fig. 76.1** The location of the pleural space in relation to the parietal and visceral pleura and the rest of the respiratory tract.

microorganisms into the pleural cavity. It has been estimated that 50% to 60% of patients develop empyema as a complication of pneumonia.

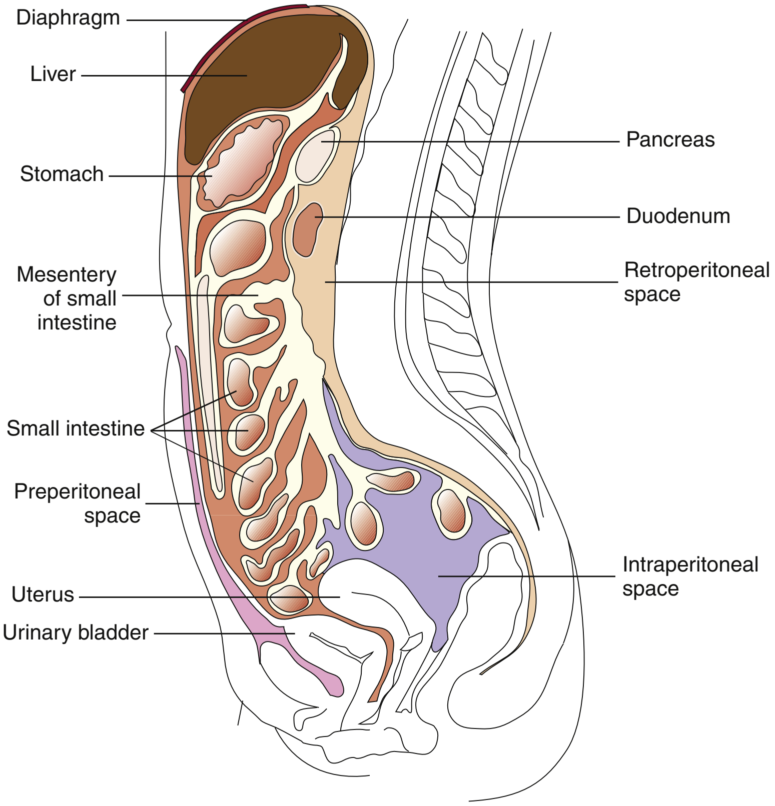
Peritoneal Fluid

The **peritoneum** is a large, moist, continuous sheet of serous membrane lining the walls of the abdominal-pelvic cavity and the outer coat of the organs contained within the cavity (Fig. 76.2). In the abdomen, these two membrane linings are separated by a space called the **peritoneal cavity,** which contains or abuts the liver, pancreas, spleen, stomach, and intestinal tract, bladder, and fallopian tubes and ovaries. The kidneys occupy a retroperitoneal (behind the peritoneum) position. Within the healthy human peritoneal cavity is a small amount of fluid that maintains the surface moisture of the peritoneum. Normal **peritoneal fluid** contains as many as 300 white blood cells per milliliter, but the protein content and specific gravity of the fluid are low. During an infectious or inflammatory process, increased amounts of fluid accumulate in the peritoneal cavity, a condition called **ascites.** Most cases of ascites are caused by liver disease, and in severe cases, the abdomen is often distended. The fluid can be collected for testing by **paracentesis** (the insertion of a needle into the abdomen and removal of fluid). The peritoneal or ascites fluid can then be analyzed for amylase, protein, albumin, cell count, nucleic acid testing, culture, and cytology. Often ascitic fluid contains an increased number of inflammatory cells and an elevated protein level.

Agents of infection gain access to the peritoneum through a perforation of the bowel, through infection within abdominal viscera, by way of the bloodstream, or by external inoculation (as in surgery or trauma). On occasion, as in pelvic inflammatory disease (PID), organisms travel through the natural channels of the fallopian tubes into the peritoneal cavity.

Primary Peritonitis

Peritonitis results when the peritoneal membrane becomes inflamed and can be either primary or secondary. **Primary peritonitis** (spontaneous bacterial peritonitis) is rare and results when infection spreads from the blood and lymph nodes with no apparent evidence of infection. The organisms likely to be recovered from patient specimens with primary peritonitis vary with the patient's age. The most common etiologic agents in children are *Streptococcus pneumoniae* and group A streptococci, Enterobacterales, other gram-negative bacilli, and staphylococci. In adults, *Escherichia coli* is the most common bacterium, followed by *Klebsiella pneumoniae, S. pneumoniae,* other streptococci species (including enterococci), and other Enterobacterales. Polymicrobic peritonitis is unusual in the absence of bowel perforation or rupture. Among sexually active young women, *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are common etiologic agents of peritoneal infection, often in the form of a **perihepatitis** (inflammation of the surface of the liver, called **Fitz-Hugh–Curtis syndrome**). Tuberculous peritonitis



• **Fig. 76.2** The abdominal cavity. The retroperitoneal and preperitoneal spaces are considered as extraperitoneal (outside) spaces. (Modified from Thibodeau GA. *Anatomy and Physiology.* St Louis: Mosby; 1993.)

occurs uncommonly in the United States and is more likely to be found among individuals who have recently traveled to South America, Southeast Asia, or Africa. Tuberculous peritonitis can occur from direct entry into the peritoneal cavity from the lymph nodes, intestine, or genital tract from patients with active disease. However, more often it is a result of hematogenous dissemination from the lungs. Fungal causes of peritonitis are not common, but *Candida* spp. may be recovered from immunosuppressed patients and patients receiving prolonged antibacterial therapy.

Secondary and Tertiary Peritonitis

Secondary peritonitis is a complication of a perforated viscus (organ), surgery, traumatic injury, loss of bowel wall integrity after a destructive disease (e.g., ulcerative colitis, ruptured appendix, carcinoma), obstruction, or a preceding infection (liver abscess, salpingitis, septicemia). The nature, location, and etiology of the underlying process govern the agents recovered from peritoneal fluid. With PID as the background, gonococci, anaerobes, or chlamydiae are isolated. With peritonitis or intraabdominal abscess, anaerobes generally are found in peritoneal fluid, usually together with Enterobacterales and enterococci or other streptococci. In patients whose bowel microbiota has been altered by antimicrobial agents, more resistant gram-negative bacilli and *Staphylococcus aureus* may be encountered. Because anaerobes outnumber aerobes in the bowel by 1000-fold, it is not surprising that anaerobic organisms play a prominent role in intraabdominal infection, perhaps acting synergistically with facultative bacteria. The organisms likely to be recovered include *E. coli,* the *Bacteroides fragilis* group, enterococci and other streptococci, *Bilophila* spp., other anaerobic gram-negative bacilli, anaerobic gram-positive cocci, and clostridia.

Tertiary peritonitis is considered when a patient with peritonitis and systemic symptoms of sepsis persists following treatment for either primary or secondary peritonitis. This condition is more common in immunosuppressed and critically ill patients. Pathogens typically isolated in these cases include organisms, such as coagulase negative staphylococci, enterococci, Enterobacterales, anaerobes, or *Candida* spp.

Peritoneal Dialysis Fluid

More than 900,000 patients with end-stage renal disease are maintained on **continuous ambulatory peritoneal dialysis (CAPD).** One in every 10 American adults, totaling more than 20 million, suffer from some type of chronic kidney disease. In this treatment, fluid is injected into the peritoneal cavity and subsequently removed, which allows exchange of salts and water and removal of various wastes in the absence of kidney function. Because the dialysate fluid is injected into the peritoneal cavity via a catheter, the break in the skin barrier places the dialysis patient at significant risk for infection. The average incidence of peritonitis in these patients is up to two episodes per year, per patient. Peritonitis is diagnosed by the presence of two of the following: cloudy dialysate, abdominal pain, or a positive culture from dialysate. Although white blood cells are usually plentiful (a value of leukocytes >100/mL is usually indicative of infection), the number of organisms is usually too low for detection on Gram stain of the peritoneal fluid sediment unless a concentrating technique is used; fungi are more readily detected. Many recent studies show that improved sensitivity can be achieved by using automated blood culture systems in which 10 mL of fluid is inoculated into culture bottles. Rapid detection of pathogens has also been successful using polymerase chain reaction (PCR) and 16s rRNA sequencing. The sensitivity associated with 16s rRNA sequencing varies significantly due to the inability to distinguish organisms due to high genetic similarity and should be used in conjunction with culture.

Most infections originate from the patient's normal skin microbiota; *Staphylococcus epidermidis* and *S. aureus* are the most common etiologic agents, followed by streptococci, aerobic or facultative gram-negative bacilli, *Candida* spp., *Corynebacterium* spp., and others. The oxygen content of peritoneal dialysate is usually too high for the development of anaerobic infection. Among the gram-negative bacilli isolated, *Pseudomonas* spp., *Acinetobacter* spp., and the Enterobacterales are commonly observed.

Pericardial Fluid

The heart and contiguous major blood vessels are surrounded by the **pericardium,** a protective tissue. The area between the **epicardium—**which is the membrane surrounding the heart muscle—and the pericardium is called the **pericardial space,** and normally contains 15 to 20 mL of clear fluid. If an infectious agent is present within the fluid, the pericardium may become distended and tight, and eventually **tamponade** (interference with cardiac function and circulation) can ensue. Up to 500 mL of fluid can accumulate during infection, which may seriously complicate cardiac function.

Agents of **pericarditis** (inflammation of the pericardium) are usually viruses, especially coxsackie virus. Bacterial pericarditis usually occurs during a severe systemic infection. Parasites, certain fungi, and noninfectious causes are also associated with this disease.

Myocarditis (inflammation of the heart muscle itself) may accompany or follow pericarditis. The pathogenesis of disease involves the host inflammatory response contributing to fluid buildup, as well as cell and tissue damage. Common causes of myocarditis include viral infections with coxsackie virus, echoviruses, or adenovirus. The most common etiologic agents of pericarditis and myocarditis are listed in Box 76.1. Other bacteria, fungi, and parasitic agents have been recovered from pericardial effusions.

Patients who develop pericarditis resulting from agents other than viruses are often immunocompromised or suffering from a chronic disease. An example is infective endocarditis, in which a myocardial abscess develops and then ruptures into the pericardial space.

• BOX 76.1 Common Etiologic Agents of Pericarditis and Myocarditis

Viruses

Enteroviruses (primary coxsackie A and B and, less commonly, echoviruses)
Adenoviruses
Influenza viruses

Bacteria (Relatively Uncommon)

Mycoplasma pneumoniae
Chlamydia trachomatis
Mycobacterium tuberculosis
Staphylococcus aureus
Streptococcus pneumoniae
Enterobacterales and other gram-negative bacilli

Fungi (Relatively Uncommon)

Coccidioides immitis
Aspergillus spp.
Candida spp.
Cryptococcus spp.
Histoplasma capsulatum

Parasites (Relatively Uncommon)

Entamoeba histolytica
Toxoplasma gondii

Joint Fluid

Arthritis is an inflammation in a joint space. Infectious arthritis may involve any joint in the body. Infection of the joint usually occurs secondary to hematogenous spread of bacteria or, less often, fungi as a direct extension of infection of the bone. It may also occur after injection of material, especially corticosteroids, into joints or after insertion of prosthetic material (e.g., total hip replacement). Although infectious arthritis usually occurs at a single site (monoarticular), a preexisting bacteremia or fungemia may seed more than one joint to establish polyarticular infection, particularly when multiple joints are diseased, such as in rheumatoid arthritis. In bacterial arthritis, the knees and hips are the most commonly affected joints in all age groups.

In addition to active infections associated with viable microorganisms within the joint, sterile, self-limited arthritis caused by antigen-antibody interactions may follow an episode of infection, such as meningococcal meningitis. When an etiologic agent cannot be isolated from an inflamed joint fluid specimen, either the absence of viable agents or inadequate transport or culturing procedures may be the cause. For example, even under the best circumstances, *Borrelia burgdorferi* is isolated from the joints of fewer than 20% of patients with Lyme disease. Nonspecific test results, such as increased white blood cell count, decreased glucose, or elevated protein, may indicate that an infectious agent is present but is inconclusive.

Bacterial

Staphylococcus aureus
Beta-hemolytic streptococci
Streptococci (other)
Haemophilus influenzae
Haemophilus spp. (other)
Bacteroides spp.
Fusobacterium spp.
Neisseria gonorrhoeae
Pseudomonas spp.
Salmonella spp.
Pasteurella multocida
Moraxella osloensis
Kingella kingae
Moraxella catarrhalis
Capnocytophaga spp.
Corynebacterium spp.
Clostridium spp.
Finegoldia spp.
Eikenella corrodens
Actinomyces spp.
Mycobacterium spp.
Mycoplasma spp.
Ureaplasma urealyticum
Borrelia burgdorferi

Fungal

Candida spp.
Cryptococcus spp.
Coccidioides immitis
Sporothrix schenckii

Viral

Hepatitis viruses
Rubella
Other viruses (rarely)

Overall, *S. aureus* is the most common etiologic agent of septic arthritis, accounting for approximately 70% of infections. In adults younger than 30 years of age, however, *N. gonorrhoeae* is commonly isolated. *Haemophilus influenzae* has been the most common agent of bacteremia in children younger than 2 years of age; consequently, it has been the most common cause of infectious arthritis in these patients, followed by *S. aureus.* The widespread use of *H. influenzae* type B vaccine has contributed to a change in this pattern. Streptococci, including groups A *(Streptococcus pyogenes)* and B *(Streptococcus agalactiae),* pneumococci, and viridans streptococci, are prominent among bacterial agents associated with infectious arthritis in patients of all ages. Among anaerobic bacteria, *Bacteroides,* including *B. fragilis,* may be recovered as well as *Fusobacterium necrophorum,* which usually involves more than one joint during sepsis. Among people living in certain endemic areas of the United States and Europe, infectious arthritis is a prominent feature associated with Lyme disease. Chronic monoarticular arthritis is commonly caused by mycobacteria, *Nocardia asteroides,* and fungi. Some of the more common etiologic agents of infectious arthritis are listed in Box 76.2.

These agents act to stimulate a host inflammatory response, which is initially responsible for the pathology of the infection. Arthritis is also a symptom associated with infectious diseases caused by certain agents, such as *Neisseria meningitidis,* group A streptococci (rheumatic fever), and *Streptobacillus moniliformis,* in which the agent cannot be recovered from joint fluid. Presumably, antigen-antibody complexes formed during active infection accumulate in a joint, initiating an inflammatory response that is responsible for the ensuing damage.

Infections in prosthetic joints are usually associated with somewhat different etiologic agents than those in natural joints. After insertion of the prosthesis, organisms that gained access during the surgical procedure slowly multiply until they reach a critical mass and produce a host response. This may occur long after the initial surgery; approximately half of all prosthetic joint infections occur more than 1 year after surgery. Normal skin bacteria are the most common etiologic agents, with *S. epidermidis,* other coagulase-negative staphylococci, *Corynebacterium* spp., and *Cutibacterium* spp. being the most prevalent. However, *S. aureus* is also a major pathogen in this infectious disease. Alternatively, organisms may reach joints during hematogenous spread from distant, infected sites.

Arthritis caused by viral agents usually occurs simultaneously with the systemic illness and may be the result of direct entry to the joint or a host immune-mediated response. Viral arthritis is associated with Parvovirus B19, Alphaviruses such as Chikungunya, rubella, hepatitis viruses B and C, HIV-1, and HTLV-1.

Diagnosis of joint infections requires an aspiration of joint fluid for culture and microscopic examination. Inoculating the fluid directly into blood culture bottles may prevent the fluid from clotting. Some of the fluid may be Gram-stained and inoculated onto blood, as well as chocolate and anaerobic media. The use of AFB (acid-fast bacteria) and fungal media must also be considered.

Bone

Bone Marrow Aspiration or Biopsy

Diagnosis of diseases, including brucellosis, histoplasmosis, blastomycosis, tuberculosis and leishmaniasis, can sometimes be made by detection of the organisms in bone marrow. *Brucella* spp. can be isolated on culture media, as can fungi, but parasitic agents must be visualized in smears or sections made from bone marrow material. Bone marrow aspirates are not likely to assist in the identification of most bacterial diseases. Many transplant centers will submit bone marrow aspirates in lysis centrifugation tubes or sterile containers for bacterial culture. If sterile containers are received, the sample should be placed in a blood culture bottle and incubated in the automated instrument. Many of the etiologic agents associated with disseminated infections in patients with human immunodeficiency virus (HIV) may be visualized or isolated from bone marrow. Some of these organisms include cytomegalovirus, *Cryptococcus neoformans,* and *Mycobacterium avium* complex.

Bone Biopsy

A small piece of infected bone is occasionally sent to the microbiology laboratory to identify the etiologic agent of **osteomyelitis** (infection of bone). Patients develop osteomyelitis from hematogenous spread of an infectious agent, invasion of bone tissue from an adjacent site (e.g., joint infection, dental infection), breakdown of tissue caused by trauma or surgery, or lack of adequate circulation followed by colonization of a skin ulceration with microorganisms. Once established, infections in bone may progress toward chronicity, particularly if blood supply is insufficient in the affected area.

S. aureus, seeded during bacteremia, is the most common etiologic agent of osteomyelitis among patients of all age groups. The toxins and enzymes produced by this bacterium, as well as its ability to adhere to smooth surfaces by expressing high-affinity adhesions to components of the bone matrix and producing a protective glycocalyx coating, contribute to the organism's pathogenicity. Osteomyelitis in younger patients is often associated with a single agent. Such infections are usually of hematogenous origin. Other organisms recovered from hematogenously acquired osteomyelitis include coagulase negative staphylococci, *Finegoldia, Salmonella* spp., *Haemophilus* spp., Enterobacterales, *Pseudomonas* spp., *F. necrophorum,* and various fungi. *S. aureus* or *P. aeruginosa* is often recovered from patients with drug addictions. Parasites or viruses are rarely, if ever, etiologic agents of osteomyelitis.

Bone biopsies from infections that have spread to a bone from a contiguous source or that are associated with poor circulation, especially in patients with diabetes, are likely to yield multiple isolates. Gram-negative bacilli are increasingly common among hospitalized patients; a break in the skin (surgery or intravenous line) may precede establishment of gram-negative osteomyelitis. Breaks in skin from other causes, such as a bite wound or trauma, also may be the initial event leading to underlying bone infection. For example, a human bite may lead to infection with *Eikenella corrodens,* whereas an animal bite may result in *Pasteurella multocida* osteomyelitis. Poor oral hygiene may lead to osteomyelitis of the jaw with *Actinomyces* spp., *Capnocytophaga* spp., and other oral microbiota, particularly anaerobes. Pigmented *Prevotella* and *Porphyromonas, Fusobacterium,* and *Finegoldia* spp. are often involved. A pelvic infection in females may result in a mixed aerobic and anaerobic osteomyelitis of the pubic bone.

Patients with neuropathy (pathologic changes in the peripheral nervous system) in the extremities—notably patients with diabetes, who may have poor circulation, may experience an unrecognized or notable trauma. They develop ulcers on the feet that do not heal, become infected, and may eventually progress to involve underlying bone. These infections are usually polymicrobial, involving anaerobic and aerobic bacteria. *Prevotella* or *Porphyromonas,* other gram-negative anaerobes, including the *B. fragilis* group, *Finegoldia* spp., *S. aureus,* and group A and other streptococci are common agents.

Nucleic acid–based testing, such as PCR, is useful in determining the infectious organism associated with the patient's condition and can be used for rapid diagnosis in conjunction with traditional culture.

• BOX 76.3 Infectious Agents in Tissue Requiring Special Media

Actinomyces spp.
Brucella spp.
Legionella spp.
Bartonella henselae (cat-scratch disease bacilli)
Systemic fungi
Mycoplasma spp.
Mycobacterium spp.
Viruses

Solid Tissues

Pieces of tissue are removed from patients during surgical or needle biopsy procedures or may be collected at autopsy. Any agent of infection may cause disease in tissue, and laboratory practices should be adequate to recover bacteria, fungi, and viruses and detect the presence of parasites. Fastidious organisms (e.g., *Brucella* spp.) and agents of chronic disease (e.g., systemic fungi and mycobacteria) may require special media and long incubation periods for isolation. Some agents requiring special supportive or selective media are listed in Box 76.3. In addition, some organisms may be visualized using histopathology, such as *Treponema pallidum, Klebsiella granulomatous*, or *Spirillum minus*. DNA sequencing and other nucleic acid–based methods are useful in the detection of organisms that cause genital ulcers or organisms that are found in complex biofilms.

Laboratory Diagnostic Procedures

Specimen Collection and Transport

Requirements for the collection and transport of specimens from sterile body sites vary because of the numerous types of specimens that can be collected and submitted to the laboratory for testing. For all specimens, the recommended procedures and transport systems for molecular detect varies and manufacturer directions should be followed accordingly.

Fluids and Aspirates

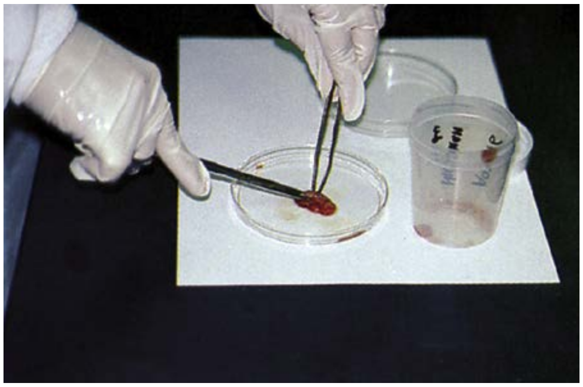
Most specimens (pleural, peritoneal, pericardial, and synovial fluids) are collected by aspiration with a needle and syringe. Collecting pericardial fluid is not without risk to the patient, because the sample is collected from the cavity immediately adjacent to the heart. Collection is performed by needle aspiration with electrocardiographic monitoring or as a surgical procedure. Laboratory personnel should be alerted in advance of the procedure, ensuring that the appropriate media, tissue culture media, and stain procedures are available immediately.

Body fluids from sterile sites should be transported to the laboratory in a sterile tube or airtight vial. Between 1 and 5 mL of specimen is adequate for isolation of most bacteria, but the larger the specimen, the better, particularly for isolation of *Mycobacterium tuberculosis* and fungi; at least 5 mL should be submitted for recovery of these organisms. Ten milliliters of fluid are recommended for the diagnosis of peritonitis. Anaerobic transport vials are available from several sources. These vials are prepared in an oxygen-free atmosphere and are sealed with a rubber septum or short stopper through which the fluid is injected. Transportation of fluid in a syringe capped with a sterile rubber stopper is not recommended. Most clinically significant anaerobic bacteria survive adequately in aerobic transport containers (e.g., sterile, screw-capped tubes) for short periods if the specimen is purulent and of adequate volume. However, collection in anaerobic transport media is recommended, and procedures vary in different laboratories. Specimens received in anaerobic transport vials should be inoculated to routine aerobic (an enriched broth, blood, chocolate, and sometimes MacConkey agar plates) and anaerobic media as quickly as possible. Specimens for recovery of fungi or mycobacteria may be transported in sterile, screw-capped tubes. At least 5 to 10 mL of fluid are required for adequate recovery of small numbers of organisms. If gonococci or chlamydia are suspected, additional aliquots should be sent to the laboratory for smears and appropriate cultures.

Percutaneous catheters are placed during many surgical procedures to prevent the accumulation of exudate and blood at the operative site. Often, the laboratory receives drainage fluids from these catheters for culture when signs and symptoms suggest infection. However, culture of such fluid is potentially misleading when the fluid becomes contaminated within the catheter or collection device, or when the fluid does not originate from a site of the infection. Direct aspiration of potentially infected fluid collections, rather than catheter drainage fluid, should be submitted for culture for the assessment of deep tissue infections in patients.

With respect to pericardial, pleural, synovial, and peritoneal fluids, the inoculation of blood culture broth bottles at the bedside or in the laboratory may be beneficial. An additional specimen should be submitted to the laboratory for a Gram stain. The specimen in the blood culture bottle is processed as a blood culture, facilitating the recovery of small numbers of organisms and diluting out the effects of antibiotics. Citrate or sodium polyanetholesulfonate (SPS) may be used as an anticoagulant. Specimens collected by percutaneous needle aspiration (paracentesis) or at the time of surgery should be inoculated into aerobic and anaerobic blood culture bottles as soon as possible.

Fluid from patients receiving CAPD can be submitted to the laboratory in a sterile tube, urine cup, or the original bag. The bag is entered with a sterile needle and syringe to withdraw fluid for culture. Fluid should be directly inoculated into blood culture bottles (20 mL recommended [10 mL in each of two culture bottles]). Numerous studies



• **Fig. 76.3** Mincing a piece of tissue for culture using sterile forceps and scissors. Note: Perform this procedure in a biosafety cabinet.

indicate that in addition to blood culture bottles, an adult Isolator tube is a sensitive and specific method for culture.

Bone

Bone marrow is typically aspirated from the interstitium of the iliac crest. Usually, this material is not processed for routine bacteria as previously indicated, because blood cultures are equally useful, and false-positive cultures for skin bacteria (*S. epidermidis*) are common. Some laboratories report good recovery from bone marrow material injected into a pediatric Isolator tube (ISOLATOR 1.5 mL, Alere, Waltham, MA) as a collection and transport device. The lytic agents within the Isolator tube are believed to lyse cellular components, presumably freeing intracellular bacteria for enhanced recovery. Bone removed at surgery or by percutaneous biopsy is sent to the laboratory in a sterile container.

Tissue

Tissue specimens are obtained after careful preparation of the skin. It is critical that biopsy specimens be collected aseptically and submitted to the microbiology laboratory in a sterile container; a wide-mouthed, screw-capped bottle or plastic container is recommended. Anaerobic organisms survive within infected tissue long enough to be recovered from culture. A small amount of sterile, nonbacteriostatic saline may be added to keep the specimen moist. Because homogenizing with a tissue grinder can destroy some organisms by the shearing forces generated during grinding, it is often best to use sterile scissors and forceps to mince larger tissue specimens into small pieces suitable for culturing (Fig. 76.3). *Legionella* spp. may be inhibited by saline. A section of lung should be submitted without saline for *Legionella* isolation.

If anaerobic organisms are of concern, a small amount of tissue can be placed into a loosely capped, wide-mouthed plastic tube and sealed into an anaerobic pouch system, which also seals in enough moisture for survival of organisms in tissue until the specimen is plated. The surgeon should take responsibility for seeing that a second specimen is submitted to anatomic pathology for histologic studies. Formaldehyde-fixed tissue is not useful for recovery of viable microorganisms, although some organisms can be recovered after very short periods of time. Material from draining sinus tracts should include a portion of the tract's wall obtained by deep curettage. Tissue from infective endocarditis should contain a portion of the valve and vegetation if the patient is undergoing valve replacement.

In some cases, contaminated material may be submitted for microbiologic examination. Specimens, such as tonsils or autopsy tissue, may be surface cauterized with a heated spatula or blanched by immersing in boiling water for 5 to 10 seconds to reduce surface contamination. The specimen may then be dissected with sterile instruments to permit culturing of the specimen's center, which will not be affected by the heating. Alternatively, larger tissues may be cut in half with sterile scissors or a blade, and the interior portion cultured for microbes.

Because surgical specimens are obtained at great risk and expense to the patient, and because supplementary specimens cannot be obtained easily, it is important that the laboratory save a portion of the original tissue (if enough material is available) in a small amount of sterile broth in the refrigerator and at −70°C (or, if necessary, at −20°C) for at least 4 weeks in case additional studies are indicated. If the entire tissue must be ground up for culture, a small amount of the suspension should be placed into a sterile tube and refrigerated.

Specimen Processing, Direct Examination, and Culture

Fluids and Aspirates

Techniques for laboratory processing of sterile body fluids are similar except for those previously discussed that are directly inoculated into blood culture bottles. Clear fluids may be concentrated by centrifugation or filtration, whereas purulent material can be inoculated directly to media. A body fluid received in the laboratory that is already clotted must be homogenized to release trapped bacteria and minced or cut to release fungal cells. Either processing of such specimens in a motorized tissue homogenizer or grinding them manually in a mortar and pestle or glass tissue grinder allows better recovery of bacteria. Hand grinding is often preferred, because motorized grinding can generate considerable heat and thereby kill microorganisms in the specimen. Grinding may lyse fungal elements; therefore, it is not recommended with specimens processed for fungi. Small amounts of whole material from a clot should be aseptically cut with a scalpel and placed directly onto media for isolation of fungi.

All fluids should be processed for direct microscopic examination. In general, if one organism is seen per oil immersion field, at least 10^5 organisms per milliliter of specimen are present. Often only a few organisms are present in normally sterile body fluids. Organisms must be concentrated in body fluids. For microscopic examination, cytocentrifugation (Fig. 70.4) should be used to prepare

Gram-stained smears, because organisms can be further concentrated up to 1000-fold. Body fluids should be concentrated by either filtration or high-speed centrifugation. Once the sample is concentrated, the supernatant is aseptically decanted or aspirated with a sterile pipette, leaving approximately 1 mL of liquid in which to thoroughly mix the sediment. Vigorous vortexing or drawing the sediment up and down into a pipette several times is required to adequately suspend the sediment. This procedure should be carried out in a biologic safety cabinet. The suspension is used to inoculate media. Direct potassium hydroxide (KOH) or calcofluor white preparations for fungi, and acid-fast stain for mycobacteria, can also be performed. (See Chapter 6 for detailed descriptions related to the preparation of smears for staining procedures.)

Specimens for fungi should be examined by direct wet preparation or by preparing a separate smear for periodic acid-Schiff (PAS) staining in addition to Gram stain. Either 10% KOH or calcofluor white is recommended for visualization of fungal elements from a wet preparation. In addition to hyphal forms, material from the thoracic cavity may contain spherules of *Coccidioides* or budding yeast cells.

Lysis of leukocytes before concentration of CAPD effluents can significantly enhance recovery of organisms. Filtration of CAPD fluid through a 0.45-mm pore membrane filter allows a greater volume of fluid to be processed and usually yields better results. Because the numbers of infecting organisms may be low (less than one organism per 10 mL of fluid), a large quantity of fluid must be processed. Sediment obtained from at least 50 mL of fluid has been recommended. If the specimen is filtered, the filter should be cut aseptically into three pieces: one of which is placed on chocolate agar for incubation in 5% carbon dioxide, one on MacConkey agar, and the other on a blood agar plate for anaerobic incubation.

If fluids have been concentrated by centrifugation, the resulting sediment should be inoculated to an enrichment broth, blood, and chocolate agars. Because these specimens are from normally sterile sites, selective media are inadvisable, because they may inhibit the growth of some organisms. Appropriate procedures for the isolation of anaerobes, mycobacteria, fungi, *Chlamydia* spp., and viruses should be used when such cultures are clinically indicated.

Bone

Clotted bone marrow aspirates or biopsies must be homogenized or ground to release trapped microorganisms. Specimens are inoculated to the same media as for other sterile body fluids. A special medium for enhancement of growth of *Brucella* spp. and incubation in 10% carbon dioxide may be needed. A portion of the specimen may be inoculated directly to fungal media. Sections are also made from biopsy material (bone) for fixation, staining, and examination (usually by anatomic pathologists) for the presence of mycobacterial, fungal, or parasitic agents. With respect to obtaining specimens from patients suspected of having osteomyelitis, cultures taken from open wound sites above infected bone, or material taken from a draining sinus leading to an area of osteomyelitis, may not reflect the actual etiologic agent of the underlying osteomyelitis. Cultures of bone samples obtained during wound debridement surgery appear to be more useful for directing antibiotic therapy for better clinical outcome.

Diagnosis of prosthetic (artificial) joint infections is often difficult. Unfortunately, there is no universally accepted definition for the diagnosis of infection in the absence of microbiologic evidence, because clinical symptoms such as pain do not differentiate infection from mechanical joint failure. There is no standardized approach to the laboratory diagnosis of these infections, and published data are conflicting. Further complicating the diagnosis is that the most common bacteria causing prosthesis infections are common skin contaminants such as coagulase-negative staphylococci. Some studies have reported that culture is relatively insensitive, possibly because of the organisms residing in biofilms, whereas PCR assays were able to detect most pathogens associated with prosthetic joint infections. Five or six operative bone specimens should be submitted for culture and three or more should yield the isolation and identification of the same organism for a definite diagnosis of infection. However, a study using PCR and culture using multiple media types and prolonged incubation found that appropriate culture was adequate to exclude bacterial infection in hip prostheses, and PCR did not enhance diagnostic sensitivity for infection.

Normal bone is difficult to break up; however, most infected bone is soft and necrotic. Grinding the specimen in a mortar and pestle may break off some pieces. Small shavings from the most necrotic-looking areas of the bone specimen may sometimes be scraped off aseptically and inoculated onto media. Pieces should be placed directly into media for recovery of fungi. Small bits of bone can be ground with sterile broth to form a suspension for bacteriologic and mycobacterial cultures. If anaerobes are to be recovered, all manipulations are best performed in an anaerobic chamber. If such an environment is unavailable, microbiologists should work quickly within a biosafety cabinet to inoculate prereduced anaerobic plates and broth with material from the bone.

Solid Tissue

Tissue should be manipulated in a laminar flow biologic safety cabinet. Processing tissue within an anaerobic chamber is even better. The microbiologist should cut through the infected area (which is often discolored) with a sterile scalpel blade. Half of the specimen can be used for fungal cultures and the other half for bacterial cultures. Both types of microbial agents should be considered in all tissue specimens. Some samples should also be sent to surgical pathology for histologic examination. Specimens should be processed for viruses or acid-fast bacilli when requested. Material that is to be cultured for parasites should be finely minced or teased before inoculation into broth. Direct examination of stained tissue for parasites is often performed in the anatomic pathology laboratory. Imprint cultures of tissues may yield bacteriologic results identical to homogenates and may help differentiate microbial infection within the tissue's center from surface colonization (growth only at the edge). Additional media can be inoculated for incubation at lower temperatures, which may facilitate recovery of certain systemic fungi and mycobacteria.

Tissue may also be inoculated to tissue culture cells for isolation of viruses. Brain, lung, spinal fluid, and blood are generally good specimens for viral isolation. Tissue may be examined by immunofluorescence for the presence of herpes simplex virus, varicella-zoster virus, cytomegalovirus, or rabies viral particles. Lung tissue should be examined by direct fluorescent antibody test for *Legionella* spp.

The tissues of all fetuses, premature infants, and babies who have died of an infectious process should be cultured for *Listeria.* Specimens of the brain, spinal fluid, blood, liver, and spleen are most likely to contain the organism.

CASE STUDY 76.1

A 79-year-old female had left-knee arthroplasty to replace an arthritic joint with a prosthetic joint. The surgery was complicated and lasted more than 1 h. She received antibiotics at the time of the surgery but not postoperatively, in accordance with usual protocols for this type of surgery. She did well postoperatively and went home in 7 days. After several weeks, she complained of low-grade fevers and pain in the joint. Her physician aspirated 50 mL of fluid from the knee and inoculated 10 mL into each of both aerobic and anaerobic blood culture bottles. Some fluid was also sent to the laboratory, where numerous white blood cells were found but no organisms were seen on Gram stain. The anaerobic blood culture bottle turned positive at 48 h. A gram-positive coccus was identified. The aerobic bottle remained negative.

Questions

1. What is the likely genus of the organism in the blood culture bottle?
2. What is the likely source of the infection in this patient?
3. The physician wanted the laboratory to be sure that the organism was not isolated because of poor technique in collection of the joint fluid specimen. Because the diagnosis of a septic joint means that the patient must have more surgery and long-term therapy, the physician wanted to be certain of the diagnosis. How can the laboratory ascertain that the organism caused the infection?

Chapter Review

1. When performing diagnostic testing on ascitic fluid, which of the following findings is expected?
- **a.** Increased number of inflammatory cells and an elevated protein level
- **b.** Decreased number of inflammatory cells and an elevated specific gravity
- **c.** Increased number of inflammatory cells and a low specific gravity
- **d.** Increased number of inflammatory cells and a low protein level

2. Which of the following groups of organisms are the leading cause of myocarditis?
- **a.** *E. coli*, the *B. fragilis* group, and enterococci
- **b.** *Mycobacteria* spp. and *Candida* spp.
- **c.** Coxsackie virus, adenovirus, and echovirus
- **d.** Influenza A and parainfluenza 1 and 3

3. Which of the following organisms are commonly responsible for peritoneal infection among young, sexually active females?
- **a.** *S. pneumoniae* and group A streptococci
- **b.** *N. gonorrhoeae* and *C. trachomatis*
- **c.** Enterobacterales and other gram-negative bacilli
- **d.** *Candida albicans* and *Candida krusei*

4. What type of fluid would be collected from the thorax body cavity?
- **a.** Thoracentesis or pleural or empyema fluid
- **b.** Paracentesis or ascitic or peritoneal fluid
- **c.** Synovial fluid
- **d.** Pericardial fluid

5. What type of fluid would be collected from the abdominal cavity?
- **a.** Thoracentesis or pleural or empyema fluid
- **b.** Paracentesis or ascitic or peritoneal fluid
- **c.** Synovial fluid
- **d.** Pericardial fluid

6. Most cases of ascites are caused by what category of disease?
- **a.** Congestive heart failure
- **b.** Kidney disease
- **c.** Pancreatic disease
- **d.** Liver disease

7. Poor dental hygiene can lead to osteomyelitis of the jaw; what organism is most often responsible for this type of infection?
- **a.** *Actinomyces* spp.
- **b.** *S. aureus*
- **c.** *Prevotella* spp.
- **d.** *Fusobacterium* spp.

8. When processing lung tissue for diagnostic culture evaluation, which of the following suspect organisms is inhibited by saline?
- **a.** *H. influenzae*
- **b.** *Legionella pneumophila*
- **c.** *S. pneumoniae*
- **d.** *K. pneumoniae*

9. Which of the following pairs of organisms is most commonly the cause of peritonitis for patients receiving CAPD therapy?
- **a.** Anaerobic bacilli and gram-negative bacteria
- **b.** *S. aureus* and *S. pyogenes*
- **c.** *S. epidermidis* and *S. aureus*
- **d.** *Actinomyces* and *Bacteroides melaninogenicus*

10. Which of the following types of organisms play a prominent role in intraabdominal infection of secondary peritonitis?
- **a.** Gram-positive cocci
- **b.** Gram-negative bacilli
- **c.** Anaerobic bacteria
- **d.** Beta-hemolytic streptococci

11. When examining fluids by direct microscopic examination, if one organism is seen per oil immersion field, how many organisms per milliliter of specimen are present?
- **a.** 55
- **b.** 75
- **c.** 105
- **d.** 155

12. When testing tissue from fetuses, premature infants, and babies who have died of an infectious process, which of the following organisms must be cultured for?
- **a.** *Cytomegalovirus*
- **b.** *Bordetella pertussis*
- **c.** *Legionella pneumophila*
- **d.** *Listeria monocytogenes*

13. True or False

_____ One colony of a potentially pathogenic microorganism may be significant when culturing fluid from normally sterile body sites.

_____ In bacterial arthritis, the knee and hip are the most commonly affected joints in all age groups.

_____ Secondary peritonitis is rare and results when infection spreads from the blood and lymph nodes.

_____ Exudative pleural effusions are caused by systemic body changes, such as congestive heart failure.

_____ Normal pleural fluid may contain as many as 300 white blood cells per milliliter.

_____ Pericarditis is often caused by parasites.

_____ *B. burgdorferi* is commonly isolated from the synovial fluid of patients with Lyme disease and joint infections.

_____ To culture bone for fungal studies, small shavings or pieces of the bone should be inoculated directly into the media.

_____ The total protein and lactate dehydrogenase measurements of pleural fluid are used for the differentiation of transudates from exudates.

_____ Parasites or viruses are rarely etiologic agents of osteomyelitis.

14. Matching: *Match each term with the correct description.*

_____ paracentesis
_____ monoarticular
_____ tamponade
_____ osteomyelitis
_____ pericarditis
_____ visceral pleura
_____ parietal pleura
_____ CAPD
_____ peritoneum
_____ ascites
_____ synovial fluid
_____ peritoneal fluid
_____ peritonitis
_____ thoracentesis
_____ effusion
_____ empyema
_____ myocarditis
_____ arthritis
_____ homeostasis

a. excess amounts of pleural fluid
b. purulent exudative pleural effusions
c. serous membrane lining walls of abdominal and pelvic cavity and outer coat of organs
d. CAPD
e. increased amounts of fluid in the peritoneal cavity
f. inflammation of the heart muscle
g. percutaneous needle aspiration
h. inflammation of the peritoneum
i. involving one joint
j. inflammation in a joint space
k. inflammation of the bone
l. inflammation of the pericardium
m. membrane covering the lungs
n. physiologic balance
o. collection of fluid from the thoracic cavity by needle aspiration
p. interference with cardiac function
q. membrane lining the entire thoracic cavity
r. joint fluid
s. fluid of the peritoneum that acts as a lubricant between the bowel, inner abdominal, and pelvic side walls

15. Short Answer

(1) Explain why a pediatric Isolator tube can be used as a collection and transport device for bone marrow specimens.
(2) Explain the difference between exudative and transudative pleural effusions.
(3) What is Fitz-Hugh–Curtis syndrome?
(4) What laboratory analysis is typically performed on pleural fluid?
(5) What factors are believed to contribute to the pathogenicity of *S. aureus* in osteomyelitis?
(6) Explain how patients develop osteomyelitis.
(7) Explain how body fluids are processed for culture in the laboratory.
(8) Why is hand grinding of tissue or clotted body fluids preferred over using a motorized tissue homogenizer?
(9) Explain why prosthetic joint infections are associated with different etiologic agents from those in natural joints.

77

Quality in the Clinical Microbiology Laboratory

OBJECTIVES

1. Distinguish between the terms total quality management (TQM), continuous quality improvement (CQI), performance improvement (PI), quality assurance (QA), LEAN, Six Sigma, and individualized quality control program (IQCP).
2. Describe the quality program associated with the microbiology laboratory.
3. Identify acceptable guidelines for specimen collection and transport and give examples of unacceptable specimens.
4. State the purpose of the Standard Operating Procedure Manual.
5. Explain the requirements for laboratory personnel, use of reference laboratories, and elements of patient reports.
6. Define proficiency testing (PT) and outline the necessary steps to achieve successful results.
7. Design a log to check performance for instruments and media used in the microbiology laboratory.
8. Explain the requirements for antimicrobial susceptibility tests (ASTs).
9. Compare the maintenance of reference-quality control stocks in bacteriology, mycology, mycobacteriology, virology, and parasitology.
10. Outline a QA program for the microbiology laboratory to include all phases of infectious disease diagnosis and differentiate between external and in-house QA audit programs.
11. Describe daily monitoring activities by microbiologists and supervisors that result in providing quality care to the patient population.

Since the publication of the report "To Err is Human" by the Institute of Medicine, the endeavor for a safer and a more efficient health care delivery system has been in full force. The issue of quality in the medical laboratory has evolved over more than four decades after the publication of the recommendations for **quality control (QC)** in 1965. Just as microbial taxonomy has changed over the years, the approach to quality has evolved as well. QC is now seen as only one part of the total laboratory quality program. Quality also includes **total quality management** (TQM), **continuous quality improvement** (CQI) **or performance improvement** (PI), **individualized quality control program** (IQCP), and **quality assurance** (QA). TQM, CQI, and PI are umbrella terms, encompassing the entire institution's quality program. TQM evolved as an activity to improve patient care by having the laboratory monitor its work to detect deficiencies and subsequently correct them. CQI, IQCP, and PI went a step further by seeking to improve patient care by placing the emphasis on preventing mistakes; CQI, IQCP, and PI advocate continuous training to guard against having to correct deficiencies. IQCP, however, goes one more step further, and allows a laboratory to determine an IQCP that may result in running QC less frequently, as long as the risk assessment demonstrates accuracy and supports the validity of the process.

The **LEAN methodology** concentrates on eliminating redundant motion, recognizing waste, and identifying what creates value from the client's perspective. The main objective for the medical laboratory is to deliver quality patient results at the lowest cost, within the shortest time frame, while maintaining client satisfaction. It involves five principles: value, value stream, flow, pull, and continuous improvement. The first principle is to define the value in the process from the client's perspective, which is what the patient knowingly pays for the attributes of service. Next, the value stream is identified for each process providing that value, challenging the wasted steps, and eliminating them. The next part involves ensuring the service flows continuously through the remaining value-added step. Then, it is all pulled together by introducing a continuous flow of events between all steps of the process where continuous flow is possible. The last principle is continuous improvement through management working toward perfection on an ongoing basis, so the number of steps and time is constantly under scrutiny. The scope of resources and the information needed to provide the service to the client needs to be monitored also. These principles can increase quality, throughput, capacity, and efficiency while decreasing cost, inventory, space, and lead time. Ultimately it will provide better patient care within the clinical laboratory.

Six Sigma is a relatively new concept compared with TQM. Six Sigma originated in 1986 from Motorola's drive to reduce defects by minimizing variation in processes through metrics measurement. The process focuses on CQIs for achieving near perfection by restricting the number of possible defects to fewer than 3.4 defects per million. Six Sigma projects follow a project methodology inspired by Deming's Plan-Do-Study-Act Cycle. The methodology is composed of five phases bearing the acronym **DMAIC:** define, measure, analyze, improve, control. The purpose is to aid in making precise measurements, identifying exact problems, and providing measurable solutions. When implemented correctly, Six Sigma can help organizations reduce operational costs by focusing on reducing defects, minimizing turnaround time, and trimming costs. The main difference between TQM and Six Sigma is the approach. TQM tries to improve quality by ensuring conformance to internal requirements, whereas Six Sigma focuses on improving quality by reducing the number of defects and impurities. Six Sigma is also fact-based, data-driven, and results-oriented, providing quantifiable and measurable bottom-line results, linked to strategy and related to customer requirements.

QC is associated with the internal activities that ensure diagnostic test accuracy. QA is associated with the external activities that ensure positive patient outcomes. Positive patient outcomes in the microbiology laboratory include:

- Reduced length of stay
- Reduced cost of stay
- Reduced turnaround time for diagnosis of infection
- Appropriate antimicrobial therapy
- Customer (physician or patient) satisfaction

CQI and PI, through well-thought-out programs of QC and QA, are part of the requirements for laboratory accreditation under Clinical Laboratory Improvement Amendments (CLIA, 1988).

IQPC provides a mechanism for the laboratory to review the preanalytical, analytical, and postanalytical phases of testing and create an individual QC process unique to the laboratory's testing and environment. An IQPC must include a risk assessment, QC, and quality assessment plan. An IQPC must assess the following:

- Specimen
- Test system
- Reagents
- Environment
- Testing personnel

CLIA does not require any specific types of tools or assessment be utilized if the laboratory demonstrates that the QC plan meets CLIA requirements. The medical laboratory director remains responsible for ensuring that the plan meets CLIA guidelines.

Quality Program

Laboratory quality is defined as accuracy, reliability, and timeliness of reported test results. The laboratory results must be as accurate as possible, all aspects of the laboratory operations must be reliable, and reporting must be timely to be useful in a clinical or public health setting. Each laboratory must establish and maintain written policies and procedures that implement and monitor quality systems for all phases of the total testing process (preanalytical, analytical, and postanalytical), as well as general laboratory systems. The medical laboratory director is primarily responsible for the QC and QA programs. However, all laboratory personnel must actively participate in both programs. Federal guidelines (CLIA, 1988) are considered minimum standards and are superseded by higher standards imposed by individual states or private certifying agencies, such as the College of American Pathologists (CAP) or The Joint Commission (TJC).

Using a set of standards established by the United States military for the manufacture and production of equipment, the International Organization for Standardization (ISO) established standards for industrial manufacturing. The ISO 9000 documents provide guidance for quality in manufacturing and service industries and can be broadly applied to many other kinds of organizations. ISO 9001:2000 addresses general quality management system requirements and applies to laboratories. There are two ISO standards that are specific to laboratories:

- ISO 15189:2007. Medical laboratories—requirements for quality and competence.
- ISO/IEC 17025:2005. General requirements for the competence of testing and calibration laboratories.

Another important international standards organization for laboratories is the Clinical and Laboratory Standards Institute, or CLSI. CLSI uses a consensus process involving many stakeholders for developing standards. CLSI has two documents that are very important in the clinical laboratory:

- QMS14-A: Quality Management System: Leadership and Management Roles and Responsibilities; Approved Guideline.
- QMS01-A4: Quality Management System: A Model for Laboratory Services; Approved Guideline—Fourth Edition.

The basic elements of a QC program are described in the following sections.

Specimen Collection and Transport

The laboratory is responsible for providing written policies and procedures that ensure positive identification and optimum integrity of a patient's specimen, from the time of collection or receipt of the specimen through completion of testing and reporting of results.

These guidelines and instructions should be available to health care providers for use when specimens are collected. The written collection instructions should be in detail and include the following:

- Test purpose and limitations
- Patient selection criteria
- Timing of specimen collection (e.g., before antimicrobials are administered)
- Optimal specimen collection sites
- Approved specimen collection methods
- Specimen transport medium criteria

- Specimen transport time and temperature
- Specimen holding instructions if it cannot be transported immediately (e.g., hold at 4°C for 24 hours)
- Minimum acceptable volume requirements where applicable
- Availability of test (onsite or sent to reference laboratory)
- Turnaround time
- Result reporting procedures

The collection instructions should include information on how a requisition should be filled out electronically or by hand, and the laboratory must include a statement indicating that the requisition must be filled out entirely. In addition to standard information, such as patient name, hospital or laboratory number, and ordering physician, other critical information includes (1) whether the patient is receiving antimicrobial therapy, (2) the suspect agent or syndrome, (3) immunization history (if applicable), and (4) travel history when certain microorganisms or parasites are suspected. The laboratory should also establish criteria for unacceptable specimens. Examples of unacceptable specimens include the following:

- Unlabeled, mislabeled, or incompletely labeled specimens
- Quantity not sufficient for testing (QNS)
- Use of an improper transport medium, such as stool for ova and parasites not submitted in preservative(s)
- Use of improper swab, such as use of wooden shaft or calcium alginate tip for viruses
- Inappropriate handling of specimen with respect to temperature, timing, or storage requirements
- Improper collection site for test requested, such as stool for respiratory syncytial virus
- Specimen leakage from transport container
- Sera excessively hemolyzed, lipemic, or contaminated with bacteria

The rejected specimen will be logged electronically or manually. A rejection of specimen report will be sent to the ordering clinician. The rejected specimens will not be returned. Sometimes, specimens not meeting the requirements may be accepted by the laboratory if the specimen is irretrievable or it has been acquired through an invasive procedure. If this happens, approval by the ordering physician and laboratory director must be secured with a disclaimer on the final report, indicating that the specimen was not collected properly, and the results should be interpreted with caution.

Standard Operating Procedure Manual

The requirement for a Standard Operating Procedure Manual (SOPM) is considered part of the QC program. The SOPM should define test performance, tolerance limits, reagent preparation, required QC, result reporting, and references. The SOPM should be written in the format of CLSI and must be reviewed and signed annually or biannually by the medical laboratory director who appears on the CLIA certificate; in addition, all changes must be approved and dated by the laboratory director. The SOPM should be available in the work areas. It is the definitive laboratory reference and is used often for questions related to individual tests. Any obsolete procedure should be dated when removed from the SOPM and retained for at least 2 years.

Personnel

It is the medical laboratory director's responsibility to employ sufficient qualified personnel for the volume and complexity of the work performed. For example, published studies regarding staffing of virology laboratories suggest one technologist per 500 to 1000 specimens per year. Technical on-the-job training must be documented, and the employee's competency must be assessed twice in the first year and annually thereafter. Continuing education programs should be provided, and verification of attendance should be maintained in the employee's personnel file. CLIA has improved the regulations associated with personnel competency (CLIA subpart K:493.1235). Laboratory employee competency assessment must include the following: (1) Direct observation of test performance, to include patient preparation (if applicable), specimen handling, processing, and testing; (2) monitoring the recording and reporting of test results; (3) review of intermediate test results or work sheets, QC results, patient results, and preventative maintenance records; (4) direct observation of performance or instrument maintenance and function checks; (5) assessment of test performance through testing previously analyzed specimens and internal blind testing of samples or external patient samples; and (6) assessment of problem-solving skills. These competency assessments must be documented and completed by qualified personnel.

Reference Laboratories

Not all testing can be completed in one facility. A laboratory test that cannot be performed in-house and needs to be sent somewhere else is considered a reference laboratory test. The reference laboratory is a separate entity from the facility that collects and sends the specimen. It must be accredited or licensed. The referral laboratory's name, address, and licensure numbers should be included on the patient's final report.

Patient Reports

There should be an established system for supervisory review of all laboratory reports. This review involves checking the specimen workup to verify that the correct conclusions were reached, and no clerical errors were made in reporting results. Reports should be released only to individuals authorized by law to receive them (physicians and various midlevel practitioners). Clinicians should be notified about "panic values" immediately. Panic values are potentially life-threatening results; for example, positive Gram stain for cerebrospinal fluid (CSF) or a positive blood culture. Reference ranges must be included on the report where appropriate. All patient records should be maintained for at least 2 years. However, maintaining records for at least 10 years may be needed to support medical necessity in the event of a postpayment billing audit by the Centers for Medicare and Medicaid Services.

Proficiency Testing

Proficiency testing (PT) is a QA measure used to monitor the laboratory's analytical performance compared with its peers and reference standards. It provides an external validation tool and objective evidence of the laboratory competence for patients, as well as accrediting and oversight agencies. Laboratories are required to participate in a PT program for each analyte (test) for which a program is available; the laboratory must maintain an average score of 80% to maintain licensure in any subspecialty area. If a new regulated analyte is added, the medical laboratory must contact the PT agency to add that analyte as soon as possible. Laboratories must remain enrolled in the same PT program for one year before changing to a different program. The federal government no longer maintains a PT program, but some states, such as New York—as well as several private accrediting agencies, such as CAP—send out "blind unknowns." These unknowns are to be treated exactly as patient specimens, from accessioning into the laboratory computer or manual logbook through workup and reporting of results. The testing personnel and medical laboratory director are required to sign a statement when the PT is completed attesting to the fact that the specimen was handled exactly like a patient specimen. In this way, PT specimens establish the accuracy and reproducibility of a laboratory's day-to-day performance. The laboratory's procedures, reagents, equipment, and personnel are all checked in the process. Furthermore, errors on PT help point out deficiencies, and the subsequent education of the staff can lead to overall improvements in laboratory quality. When scores (evaluations) come back, critiques accompanying them should be discussed with the entire technical staff. Evidence of corrective action in the event of problems should be documented, including changes in procedures, retraining of personnel, or the purchase of alternative media and reagents.

Some laboratories have a system of internal PT in addition to those received from external agencies. When external audit is not available for a testing method, laboratories are required by law to set up an internal program to revalidate the test, at least semiannually. Internal PT samples can be set up by (1) seeding a simulated specimen and labeling it as an autopsy specimen so that no one panics if a pathogen is recovered, (2) splitting a routine specimen for workup by two different technologists, or (3) sending part of a specimen to a reference laboratory to compare and confirm the laboratory's result.

Performance Checks

Instruments

Instruments and equipment logs should contain the following information:

- Instrument name, serial number, and date of implementation in the laboratory.
- Procedure and periodicity of function checks with at least the frequency specified by the manufacturer; function checks must be within the manufacturer's established limits before patient testing is conducted.
- Acceptable performance ranges.
- Instrument function failures, including specific details of steps taken to correct the problems (corrective action).
- Date and time of service requests and response.
- Maintenance records as defined and with at least the minimum frequency specified by the manufacturer.

In addition, with the advances in technology, some instruments have on-board controls that are intended to be the same procedure as using external QC material. If the material represents a similar matrix to the patient samples, and the material goes through the exact same testing procedure, the on-board controls may be used to satisfy the previous need for external QC. It is the medical laboratory director's responsibility to ensure that the material used meets all regulatory requirements.

Instrument maintenance records should be retained in the laboratory for the life of the instrument. Specific guidelines regarding the periodicity of testing for autoclaves, biologic safety cabinets, centrifuges, incubators, microscopes, refrigerators, freezers, water baths, heat blocks, and other microbiology laboratory equipment can be found in a few of the references listed at the end of this chapter.

Commercially Prepared Media Exempt From Quality Control

The CLSI Subcommittee on Media Quality Control collected data over several years regarding the incidence of QC failures of commonly used microbiology media. Based on its findings, the subcommittee published a list of media that did not require retesting in the user's laboratory if purchased from a manufacturer who follows CLSI guidelines. The laboratory must inspect each shipment for cracked media or Petri dishes, hemolysis, freezing, unequal filling, excessive bubbles, clarity, and visible contamination. The manufacturer must supply written assurance that CLSI standards were followed; this verification must be maintained along with the laboratory's QC protocol.

User-Prepared and Nonexempt, Commercially Prepared Media

QC forms for user-prepared media should contain the amount prepared, the source of each ingredient, the lot number, the sterilization method, the preparation date, the expiration date (usually 1 month for agar plates and 6 months for tubed media), and the name of the preparer. Both user-prepared and nonexempt, commercially prepared media should be checked for proper color, consistency, depth, smoothness, hemolysis, excessive bubbles, and contamination. A representative sample of the lot should be tested for sterility; 5% of any lot is tested when a batch of 100 or fewer units is received, and a maximum of 10 units are tested in larger batches. A batch is any one shipment of a product with the same lot number; if a separate shipment of the same lot number of a product is received, then it is considered a different batch and needs to be tested separately.

Sterility is examined by incubating the medium for 48 hours under the environmental conditions and temperature routine used within the laboratory. Both user-prepared and nonexempt, commercially prepared media should also be tested with QC organisms of known physiologic and biochemical properties. Tables listing specific organisms to test for various media can be found in a few of the references listed at the end of this chapter.

Antimicrobial Susceptibility Tests

The goal of QC testing of antimicrobial susceptibility tests (ASTs) is to ensure the precision and accuracy of both the supplies and the microbiologists performing the test. The laboratory must check each lot number and shipment of antimicrobial agent(s) before, or concurrent with, initial use, using approved control organisms. Criteria regarding frequency of testing are the same regardless of the methodology, such as minimum inhibitory concentration (MIC) broth dilution or Kirby-Bauer (Chapter 11). Each new shipment of microdilution trays or Mueller-Hinton plates should be tested with CLSI-approved American Type Culture Collection (ATCC [Rockville, MD]) reference strains.

Reference strains for MIC testing are selected for genetic stability and give MICs within the midrange of each antimicrobial agent tested. Reference strains for Kirby-Bauer testing have clearly defined mean diameters for the respective zone of inhibition for each antimicrobial tested. ATCC numbers of reference strains are different for various AST methods. QC MICs and zone diameters are annually updated and published by the CLSI Subcommittee on Antimicrobial Susceptibility Testing. New tables should be obtained from the CLSI regularly.

Each susceptibility test system must also be tested with use (usually daily) for 20 consecutive days. If three or fewer MICs or zone of inhibition diameters per drug-reference strain combination are outside the reference range during the 20-day testing period, laboratories may switch to weekly QC testing. Thereafter, aberrant results obtained during the weekly testing must be vigorously investigated. If a source of error, such as contamination, incorrect reference strain used, or incorrect atmosphere of incubation is found, QC testing may simply be repeated. However, if no source of error is uncovered, 5 consecutive days of retesting must be performed. If accuracy and precision are again acceptable, weekly QC testing may resume; if the problem drug/organism combinations are still outside the reference ranges, 20 days of consecutive testing must be reinitiated before weekly testing can be reinstated. Under no circumstances should any drug/organism combination be reported for a patient isolate if QC testing has failed.

Stains and Reagents

Containers of stains and reagents should be labeled as to contents, concentration, storage requirements, date prepared (or received), date placed in service (commonly called the "date opened"), expiration date, source (commercial manufacturer or user prepared), and lot number. All stains and reagents should be stored according to the manufacturer's recommendations and tested with positive and negative controls before use. Tables listing specific organisms to test for various stains or reagents can be found in several references at the end of this chapter. Outdated materials or reagents that fail QC even after retesting with fresh organisms should be discarded immediately. Patient specimens should not be tested using the lot number in question until the problem is resolved; in the case of a repeat failure, an alternative method should be used, or the patient's specimen should be sent to a reference laboratory.

Antisera

The lot number, date received, condition received, and expiration date must be recorded for all shipments of antisera. In addition, the antisera should be dated when opened. New lots must be tested concurrently with previous lots, and testing must include positive and negative controls. Periodicity of testing thereafter should follow the requirements of agencies that inspect an individual laboratory and may include with use, monthly, or semiannual checks.

Kits

Kits that have been approved by the US Food and Drug Administration (FDA) need to be tested as specified in the manufacturer's package insert. Each shipment of kits must be tested even if it is the same lot number as a previously tested lot, because temperature changes during shipment may affect the performance. Components of reagent kits of different lot numbers must not be interchanged unless otherwise specified by the manufacturer.

Maintenance of Quality Control Records

All QC results should be recorded and, when applicable, must include a review of the effectiveness of corrective actions taken to resolve problems, revision of policies and procedures necessary to prevent recurrence of problems, and discussion with appropriate staff. If temperature is adjusted or a biochemical test is repeated, the new readings within the tolerance limits should be listed. In many laboratories, the supervisor reviews and initials all forms weekly; the director then reviews each one monthly. QC records should be maintained for at least 2 years, except those on equipment, which must be saved for the life of each instrument.

Maintenance of Reference Quality Control Stocks

Stock organisms may be obtained from the ATCC, commercial vendors, or PT programs; well-defined clinical isolates may also be used. The laboratory should have enough organisms on hand to cover the full range of testing of all necessary materials, such as media, kits, and reagents.

Bacteriology

Nonfastidious, aerobic bacterial organisms can be saved up to 1 year on trypticase soy agar (TSA) slants. Long-term storage (less than 1 year) of aerobes or anaerobes can be accomplished either by lyophilization (freeze drying) or freezing at −70°C. Frozen, nonfastidious organisms should be thawed, re-isolated, and refrozen every 5 years; fastidious organisms should be thawed, re-isolated, and refrozen every 3 years. Stock isolates may be maintained by freezing them in 10% skim milk; trypticase soy broth (TSB) with 15% glycerol; 10% horse blood in sterile, screw-cap vials; or the Microbank commercially available system (Pro Lab Diagnostics, Round Rock, TX).

Mycology

Yeasts may be treated as nonfastidious bacterial organisms for maintaining stock cultures. Molds can be stored on potato dextrose agar (PDA) slants at 4°C for 6 months to 1 year. For longer-term storage, PDA slants may be overlaid with sterile mineral oil and stored at room temperature. Alternatively, sterile water can be added to an actively sporulating culture on PDA, the conidia (spores) can be teased apart to dislodge them from the agar surface, and the water can then be dispensed to sterile, screw-top vials. These vials should be capped tightly and stored at room temperature.

Mycobacteriology

Acid-fast bacilli (AFB) may be kept on Lowenstein-Jenson (LJ) agar slants at 4°C for up to 1 year. They may also be frozen at −70°C in 7H9 broth with glycerol.

Virology

Viruses may be stored indefinitely at −70°C in a solution containing a cryoprotectant, such as 10% dimethyl sulfoxide (DMSO) or fetal bovine serum.

Parasitology

Slides and photographs must be available for QC purposes. Trichrome and other permanent slides may be purchased from commercial vendors. Clinical slides may be preserved indefinitely by adding a drop of Permount and a coverslip. Clinical slides prepared in-house should be inspected periodically, because the preservation solution may deteriorate and crack over time.

Quality Assurance Program

Because QA is the method by which the overall process of infectious disease diagnosis is reviewed, any of the steps involved in the diagnosis of an infectious disease may be studied. These steps include the following phases:

- Preanalytical Phase
  - Ordering of test by the clinician
  - Processing of test by the clinician
  - Processing of test request by the clerical staff
  - Collection of specimen by health care providers or patients
  - Transport of specimen to the laboratory
  - Initial processing of specimen in the laboratory, including specimen accessioning
- Analytical Phase
  - Examination and workup of culture by the microbiologist
  - Interpretation of specimen results by the microbiologist
- Postanalytical Phase
  - Formulation of a written or printed report by the microbiologist
  - Communication of the microbiologist's conclusions to the clinician in written or printed format
  - Interpretation of report by the clinician
  - Institution of appropriate therapy by the clinician

Analytical testing (the work completed in the microbiology laboratory) is now seen as only one part of a continuing spectrum of steps that begins when the physician orders the test and ends when he or she receives the results and treats the patient.

QA audits are planned and conducted by examining the three phases of testing. The goal is to look at the proficiency with which the patient is served by the whole facility, including the laboratory. The outcome is to look at the consequences to the patient based on the work that was performed. QA audits involve an analysis of how the system works and how it can be improved.

Types of Quality Assurance Audits

One way to conduct a QA audit is for the laboratory to subscribe to an external interlaboratory QA program. Topics to be audited are selected nationally. Data are then collected for a specified period and then returned to the program provider for analysis. A summary is compiled and returned to the institution with a comparison with other facilities of similar size and scope of service. That way, an individual facility can compare its results with those of its peers, a process called **benchmarking.** QA audits in microbiology may include areas such as (1) blood culture use, (2) health care–associated infections, (3) cumulative susceptibility results, (4) antibiotic usage, (5) turnaround time for CSF Gram stains, (6) viral hepatitis test use, (7) laboratory diagnosis of tuberculosis, (8) blood culture contamination rates, (9) appropriateness of the ordering of stools for microbiology testing, and (10) sputum quality. Other laboratory-wide audits are also applicable to the microbiology laboratory, including error reporting, quality of reference laboratories, and effects of laboratory computer downtime. A facility that does not subscribe to an external program may select topics for audits through suggestions from the medical, nursing, or pharmacy staff; complaints from the medical or nursing staff; or deficiencies and/or observations noted in the laboratory.

Physicians may suggest an audit to measure the transcription accuracy of their orders by nursing unit clerical personnel. Nursing administrators may suggest an audit of contaminated urine cultures to assess the compliance of the nursing staff in instructing patients about proper urine culture collection techniques. Pharmacists may notice improper antibiotic use by the clinical staff—for example, a patient was not placed on the appropriate therapy after the pathogen was reported or the patient remains on antibiotic therapy to which his or her organism is resistant after the susceptibility report has been charted. Complaints from the medical or nursing staff can involve failure of the laboratory to conduct all the tests requested on the requisition, performance of the wrong test, or an unexpected delay in turnaround time of test results. All complaints to the laboratory must be documented. Corrective action and follow-up with the laboratory, medical, and nursing staff must also be documented.

Deficiencies or problems in the laboratory's performance should also be documented. If, for example, the laboratory notices a dramatic and unseasonable rise in the number of positive respiratory syncytial virus (RSV) direct antigen tests in the summer, and the problem is traced back to a QC problem that a new employee did not recognize, a QA audit might be indicated to study the outcome of the patients, including inappropriate treatment for RSV and failure to institute treatment for the true causative agent. Alternatively, microbiologists may notice they are receiving many ova and parasite (O&P) examinations and stool cultures on patients hospitalized for more than 3 days. Because current cost containment guidelines suggest that this is inappropriate, the microbiology laboratory personnel could undertake a study to determine the percentage of positive results and the number of patients who tested positive for *Clostridiodes difficile* cytotoxin, which is the more likely cause of diarrhea in patients hospitalized for more than 3 days. If the audit showed that none of the stool cultures or O&P examinations tested positive and no stools were analyzed for *C. difficile* cytotoxin, then these findings would be presented to the medical staff. Some months after the medical staff in-service, the number of stool culture and O&P requests on patients hospitalized longer than 3 days would be reevaluated in the hope of a dramatic decrease in numbers of inappropriate tests.

Conducting a Quality Assurance Audit

Box 77.1 is an example of how an in-house QA audit may be conducted.

Continuous Daily Monitoring

Daily activities of microbiologists and supervisory personnel ensure that patients get the best quality care. These activities include (1) comparing results of morphotypes seen on direct examinations with what grows on the culture to ensure that all organisms have been recovered, (2) checking antimicrobial susceptibility reports to verify that profiles match those expected from a species, and (3) studying culture and susceptibility reports for clusters of patients with unusual infections or multidrug-resistant organisms. These and many other processes result in continual improvement to all test systems, ultimately resulting in quality patient care.

• BOX 77.1 Quality Assurance Audit on STAT[a] Turnaround Times

Background

After a complaint regarding turnaround time for STAT RSV direct antigen tests one winter, the microbiology laboratory at General Hospital has decided to audit its turnaround time. The medical staff indicated that it would like to turn the test around in 2.5 h (150 min) from the time of collection to the time the physician is notified; the medical staff feels that this will ensure the maximum patient benefits.

Study Design

All RSV requests for direct antigen testing were evaluated for a 3-month period to determine whether laboratory personnel were meeting this turnaround time.

Results

	REPORTS GIVEN IN <150 MINUTES		REPORT TIME EXCEEDING 150 MINUTES		COMBINED AVERAGES	
Month	**Number of Specimens**	**Average Time**	**Number of Specimens**	**Average Time**	**Number of Specimens**	**Average Time**
December	57	114 min	15	195 min	72	130 min
January	114	108 min	14	179 min	128	116 min
February	70	114 min	3	165 min	73	116 min

Analysis

In all, 273 reports were reviewed. The average reporting time for the 3-month period was under the acceptable 150 min. In December and January, 15 and 14 specimens, respectively, had turnaround times that exceeded 150 minutes, with an average of 195 min in December and 179 min in January; in February, 3 reports exceeded 150 min.

Conclusions

The overall (combined) average reporting time, although remaining within 150 min, could be improved. There was a dramatic drop in February after the medical staff complaint. This was undoubtedly a result of in-services given to courier and clerical staff regarding the need to transport and accession the STAT specimens quickly.

Recommendations

Because hospital-wide systems have been improved, appropriate follow-up would be to audit the STAT turnaround time for another test—for example, Gram stain of cerebrospinal fluid—in 3 to 6 months to verify that it also meets the 150-min turnaround time requirement.

Chapter Review

1. Which of the following statements describes the term Six Sigma?
   - **a.** Six Sigma drives toward reducing defects by maximizing variation in processes through metrics measurement.
   - **b.** Six Sigma focuses on achieving perfection by eliminating the number of possible defects.
   - **c.** Six Sigma is based on DMAIC (define, measure, analyze, improve, control), which helps in making precise measurements, identifying exact problems, and providing solutions that can be measured.
   - **d.** Six Sigma can guarantee that organizations will lower operational costs by focusing on reducing defects, minimizing turnaround time, and trimming costs.
2. Development and implementation of a laboratory quality program is ultimately the responsibility of:
   - **a.** The laboratory director
   - **b.** The microbiology laboratory supervisor
   - **c.** The microbiology laboratory personnel
   - **d.** The Joint Commission
3. A urine specimen was received in an appropriate container. The specimen was properly labeled with patient information, but it leaked in the protective biohazard bag. What should the microbiologist do?
   - **a.** Accept the specimen and process it according to instructions
   - **b.** Accept the specimen but add a disclaimer to the report
   - **c.** Request a health care provider to identify the specimen and process it
   - **d.** Reject the specimen and request a new one
4. What is the purpose of the SOPM?
   - **a.** States test performance and tolerance limits
   - **b.** Describes reagent preparation and required QC
   - **c.** Defines result reporting and references
   - **d.** All the above
5. Patient reports are official documentations that must be maintained for a minimum period of:
   - **a.** 1 year
   - **b.** 2 years
   - **c.** 10 years
   - **d.** Indefinitely
6. Which of the following statements does *not* accurately describe PT?
   - **a.** PT is an optional requirement for laboratories to validate accuracy of performance.
   - **b.** PT is an external validation tool and objective evidence of the laboratory competency.
   - **c.** The laboratory must maintain an average score of 80% to maintain licensure in any subspecialty area.
   - **d.** PT specimens must be treated exactly as patient specimens, from accessioning into the laboratory computer or manual logbook through workup and reporting of results.
7. Equipment logs should contain the following performance checks *except:*
   - **a.** Instrument name, serial number, and date put in service
   - **b.** Name and social security number for each user
   - **c.** Maintenance records as defined by the manufacturer and with at least the frequency specified by the manufacturer
   - **d.** Acceptable performance ranges
8. Why are CLSI-approved ATCC reference strains used for QC?
   - **a.** They are reasonably priced
   - **b.** They are readily available from many laboratory vendors
   - **c.** They produce reliable results over time
   - **d.** They can be frozen
9. A QA program measures the overall process of infectious disease diagnosis by reviewing the:
   - **a.** Preanalytical phase
   - **b.** Analytical phase
   - **c.** Postanalytical phase
   - **d.** All three phases of testing
10. **True or False**

    ___The goal of QC testing of ASTs is to ensure the precision and accuracy of both the supplies and the microbiologists performing the test.
11. **Short Answer:** Describe three continuous monitoring activities that can lead to an improved patient quality care.

78

Infection Control

OBJECTIVES

1. Define and compare health care–associated infections and community-acquired infections.
2. List three factors that determine the likelihood that a given patient would acquire a health care–associated infection.
3. State the most common types of health care–associated infections and identify the risk factors that predispose patients to acquire each infection.
4. Explain the emergence of antibiotic-resistant microorganisms and their impact on health care.
5. Describe hospital infection control programs and outline the structure and responsibilities of the infection control committee in a medical facility.
6. Identify the means of transmission for microorganisms within a health care facility.
7. Interpret the role of the microbiology laboratory in an infectious disease outbreak.
8. Compare the two major ways to characterize microorganism strains involved in an outbreak.
9. Discuss techniques for isolation precautions used to prevent the spread of health care–associated infections.
10. Identify potential useful applications for surveillance cultures.
11. Explain the contribution of the environment to health care–associated and community-associated infections. In your explanation, discuss the importance of a multimodal approach to reducing these infections.
12. Discuss the role of federal influences on state-level health care–associated infections program initiatives and reporting activities.
13. Identify health care worker infection and illness reporting mandates.

It is estimated that between 1.75 and 3 million (5% to 10%) of the 35 million patients admitted annually to acute-care hospitals in the United States acquire an infection that was neither present nor in the prodromal (incubation) stage when they entered the hospital. These infections are called **health care–associated infections (HAIs).** HAI has replaced old confusing terms such as nosocomial, hospital-acquired, or hospital-onset infections. Treatment of HAI is estimated to add between $4.5 and $15 billion annually to the cost of health care and represents an enormous economic problem in today's environment of cost containment. The societal cost of HAIs in acute-care hospitals in the United States has been estimated at $96 to $147 billion per year. In addition, many of these infections lead to the death of hospitalized patients (patient mortality) or, at minimum, additional complications (patient morbidity) and further antimicrobial chemotherapy.

Some of the earliest efforts to control infection followed the recognition in the 19th century that women were dying in childbirth from bloodstream infections caused by group A streptococcus *(Streptococcus pyogenes)* because physicians were spreading the organism by failing to wash their hands between examinations of different patients. Hand washing is still a key component of a modern **multimodal infection control** program. Moreover, the first recommendations for isolation precautions in US hospitals were published in the late 1800s, when guidelines appeared advocating placement of patients with infectious diseases in separate hospital facilities. By the late 1950s, the advent of HAI caused by *Staphylococcus aureus* finally ushered in the modern age of infection control. In the past four decades, we have learned that, in addition to hospitalized patients acquiring infections, health care workers (HCWs) are also at risk of acquiring infections from patients. Thus, present-day infection control and prevention programs have evolved to prevent the acquisition of infection by patients and caregivers. To be successful, a multimodal approach must be supported by the hospital administration (the C-suite) and involve all departments on an enterprise-wide basis.

In contrast, **community-acquired infection** is an infection contracted outside a health care setting or an infection present on admission. Community-acquired infections are often distinguished from HAIs by the types of organisms that affect patients who are recovering from a disease or infection. Community-acquired respiratory infections commonly involve strains of *Haemophilus influenzae* or *Streptococcus pneumoniae* and are usually more sensitive to antibiotic treatment.

The American Recovery and Reinvestment Act of 2009 was signed into law on February 17, 2009. The Recovery Act was designed to stimulate economic recovery in various ways, including strengthening the nation's health care infrastructure and reducing health care costs. Within the Recovery Act, $50 million was authorized to support states in the prevention and reduction of HAI. For example, 2014 funding supported state HAI infrastructure; antimicrobial stewardship; prevention of *Clostridioides difficile,* carbapenem-resistant Enterobacterales (CRE), and hemodialysis bloodstream infections; HAI data validation; and promotion of safe injection practices. Many have considered the federal funding a critical resource for the development and proper functioning of state HAI programs.

Usually HAI data reporting occurs on the state level, but federal reporting requirements also exist. Federal reporting of HAIs by hospitals is required under the Centers for Medicare and Medicaid Services (CMS) Inpatient Quality Reporting Program (IQR Program). The IQR Program, which began in 2010, was developed under the Medicare Prescription Drug, Improvement and Modernization Act of 2003. The Deficit Reduction Act added new requirements. Medicare-certified facilities ("subsection (d)" hospitals) are required to submit data on specific quality measures, including HAIs, to receive full reimbursement. The CMS has set a goal of reducing HAI conditions by 20% from 2014 through 2019. To reach its goal, CMS is assisting many hospitals through Hospital Improvement Innovation Networks. The networks collaborate with federal agencies, private partners, and patient advocacy organizations to make hospital care safer. Consequently, HAIs continued to decline according to the latest national scorecard released by the Agency for Healthcare Research and Quality (AHRQ). The overall rate decreased dramatically from 2010 through 2016, resulting in fewer deaths and significant cost savings. However, rates of certain HAI conditions, such as pressure ulcers, rose in recent years.

Incidence of Health Care–Associated Infections

The Centers for Disease Control and Prevention (CDC) has established the National Healthcare Safety Network (NHSN) program to monitor the incidence of HAI in the United States. Data collected in NHSN are used to improve patient safety at the local and national levels. In aggregate, the CDC analyzes and publishes surveillance data to estimate and characterize the national burden of HAIs. Regardless of a hospital's size or medical school affiliation, the rates of infections at each body site are consistent across institutions. The system currently serves more than 13,000 medical facilities. The CDC plans on expanding the NHSN to more than 17,000 facilities. As part of that plan, the CDC will continue its efforts to work with state and local health departments to assist with NHSN data collection and implementation of prevention strategies.

Facilities participating in the IQR Program are required to use the NHSN for reporting HAI data. Hospitals must enroll in the program and complete NHSN training to comply with these federal regulations. After HAI data are collected, they are publicly reported on a federal website called Hospital Compare.

Most HAIs are urinary tract infections (UTIs; 33%), followed by pneumonia (15%), surgical site infections (15%), and bloodstream infections (13%). The remaining 24% are other miscellaneous infections. On average, each HAI adds 5 to 10 days to the affected patient's hospital stay. Of individuals with hospital-acquired bloodstream or lung infections, 40% to 60% die each year. Likewise, patients with indwelling urinary catheters have a threefold increased chance of dying from urosepsis—a bloodstream infection that is a complication of a UTI—than those who do not have one.

Infection rates vary according to hospital type. Large, tertiary-care hospitals that treat the most seriously ill patients often have higher rates of HAI than do small, acute-care community hospitals; large medical school–affiliated (teaching) hospitals have higher infection rates than do small teaching hospitals. This difference in the risk of infection is probably related to several factors, including but not limited to the severity of illness, the frequency of invasive diagnostic and therapeutic procedures, and variation in the effectiveness of infection control programs. Within hospitals, the surgical and medical services have the highest rates of infection, whereas the pediatric and nursery services have the lowest. Moreover, within services, the predominant type of infections varies—that is, surgical site infections are the most common on the surgical service, whereas urinary tract or bloodstream infections are the most common on medical services or in the nursery.

Types of Health Care–Associated Infections

Most HAIs are endogenous in origin—that is, they involve the patient's own microbiota. Three principal factors determine the likelihood that a given patient will acquire an infection:

- Susceptibility to infection and/or immune status of the patient
- The virulence of the infecting organism
- The nature of the patient's exposure to the infecting organism

In general, hospitalized individuals have increased susceptibility to infection. Corticosteroids, cancer chemotherapeutic agents, and antimicrobial agents all contribute to the likelihood of HAI by suppressing the immune system or altering the host's normal microbiota to that of resistant microbes. Likewise, foreign objects, such as urinary or intravenous catheters, impair or physically circumvent the body's natural barriers to infection. Nonetheless, these medications or devices are necessary to cure the patient's primary medical condition. Finally, exerting influence over the virulence of the pathogens is not possible because it is not possible to immunize patients against HAI. Patients with serious community-acquired infections are commonly admitted to the hospital, and the disease may spread by either direct contact; by contact with contaminated food, water, medications, or medical devices (fomites); or by airborne transmission. Thus, the HAI may never be completely eliminated, only controlled.

Catheter-Associated Urinary Tract Infections

UTIs are the most common type of health care–associated infection reported to the NHSN. Among UTIs acquired in the hospital, approximately 75% are associated with a urinary catheter. Gram-negative rods produce most health care–associated UTIs, and *Escherichia coli* is the number one organism involved. Gram-positive organisms, *Candida* spp., and other fungi cause the remainder of the infections. The risk factors that predispose patients to acquire a health care–associated UTI include advanced age, female gender, severe underlying disease, and the placement of indwelling urinary catheters.

Ventilator-Associated Pneumonia (VAP)

The most common HAI pathogens that cause pneumonia include gram-negative rods, *S. aureus,* and *Moraxella catarrhalis. S. pneumoniae* and *H. influenzae,* which cause most community-acquired pneumonias, are not important etiologic agents in health care–associated infections except very early during the hospital course (first 2 to 5 days); these infections probably represent infections that were already incubating at the time of hospital admission. The risk factors that predispose patients to acquire a health care–associated lung infection include advanced age, chronic lung disease, large-volume aspiration (the microorganisms in the upper respiratory tract are aspirated into the lungs instead of being spit out or swallowed), chest surgery, hospitalization in intensive care units, and intubation (placement of a breathing tube down a patient's throat), or attachment to a mechanical ventilator (which controls breathing).

Surgical Site Infections

Approximately 4% of surgical patients develop surgical site infections; 50% of these infections develop after the patient has left the hospital, so this number is likely an underestimate of the true prevalence of infection. Gram-positive organisms (*S. aureus,* coagulase-negative staphylococci, and enterococci) cause most of these infections, followed by gram-negative rods and *Candida* spp. The risk factors that predispose patients to acquire a health care–associated wound infection include advanced age, obesity, infection at a remote site (that spreads through the bloodstream), malnutrition, diabetes, extended preoperative hospital stay, longer than 12 hours passing between preoperative shaving of the site and surgery, extended time of surgery, and inappropriate timing of prophylactic antibiotics (given to prevent common infections before they seed the surgical site). Surgical wounds are classified as clean, clean-contaminated, contaminated, or dirty, depending on the number of potentially contaminating organisms at the site. Bowel surgery is considered "dirty," for example, whereas surgery for a total hip replacement is considered "clean."

Central Line–Associated Bloodstream Infections

A central line–associated bloodstream infection is a serious infection that occurs when microbes enter the bloodstream through a central line. A central line is a tube that health care providers place in a large vein in the neck, chest, or arm to give fluids, blood, or medications or to do certain medical tests quickly. CLABSIs result in thousands of deaths each year and billions of dollars in added costs to the US health care system, yet these infections are preventable. The risk factors that predispose patients to acquire a CLABSI include age 1 year or younger or 60 years or older, malnutrition, immunosuppressive chemotherapy, loss of skin integrity (e.g., burn or decubiti [bedsore]), severe underlying illness, indwelling device (e.g., catheter), intensive care unit stay, and prolonged hospital stay.

Emergence of Antibiotic-Resistant Microorganisms

Antibiotic resistance is one of the biggest public health challenges in recent years. Each year in the United States, at least 2 million people get an antibiotic-resistant infection, and at least 23,000 people die. In most cases, antibiotic-resistant infections require extended hospital stays and costly and toxic alternatives. Fighting this threat is a public health priority that requires a collaborative global approach across sectors. Antibiotic resistance happens when microorganisms develop the ability to defeat the drugs designed to kill them.

Antibiotic resistance does not mean the body is becoming resistant to antibiotics; it is that organisms have become resistant to the antibiotics designed to kill them. The organisms that cause HAIs have changed over the years because of selective pressures from the use (and overuse) of antibiotics (Chapter 10). Risk factors for the acquisition of highly resistant organisms include prolonged hospitalization and prior treatment with antibiotics. In the preantibiotic era, most HAIs were caused by *S. pneumoniae* and group A *Streptococcus (S. pyogenes).* In the 1940s and 1950s, with the advent of treatment of patients with penicillin and sulfonamides, resistant strains of *S. aureus* appeared. Then, in the 1970s, treatment of patients with narrow-spectrum cephalosporins and aminoglycosides led to the emergence of resistant aerobic gram-negative rods, such as specific species of *Klebsiella, Enterobacter, Serratia,* and *Pseudomonas.* During the late 1970s and early 1980s, the use of more potent cephalosporins played a role in the emergence of antibiotic-resistant, coagulase-negative staphylococci, enterococci, methicillin-resistant *S. aureus* (MRSA), and *Candida* spp. Similarly, the 1990s witnessed the emergence of beta-lactamase-producing, high-level gentamicin-resistant, and vancomycin-resistant enterococci (VRE). The 21st century has seen the emergence of vancomycin-resistant *S. aureus* (VRSA) and CRE, which include normal microbiota of the gastrointestinal tract that are highly resistant to antibiotics.

The patients' microbiome changes quickly after hospitalization from viridans streptococci, saprophytic *Neisseria* spp., and diphtheroids to potentially resistant microorganisms found in the hospital environment. The colonized nares, skin, gastrointestinal tract, or genitourinary tract can later serve as reservoirs for endogenously acquired infections. Moreover, if patients colonized with resistant microorganisms return to nursing homes in the community harboring these organisms, they can also transfer them to other patients. This further increases the pool of patients who harbor multidrug-resistant organisms when they, in turn, are hospitalized. These new patients contaminate the hospital environment and serve as potential reservoirs for spread to additional patients.

Hospital Infection Control Programs

Hospital or health care facility infection control programs are designed to detect and monitor HAIs and to prevent or control their spread. The major responsibilities for an infection control program include surveillance, environmental monitoring, continuous quality improvement, consultation, outbreak and isolation management, regulatory compliance, and education. Infection control programs are usually headed by an infection control professional. This person should possess knowledge of epidemiology statistics, patient care practices, occupational health, sterilization, disinfection, and sanitation, infectious diseases, microbiology, education, and management. To plan and coordinate these responsibilities, many programs include multidisciplinary support teams to carry out many of the functions. The infection control team is usually headed by an infection control practitioner (often a nurse or laboratory practitioner with special training), and should include a microbiologist, an epidemiologist (usually an infectious disease physician), the dietary manager, a pharmacist, the chief nursing officer, operating room manager (when applicable), and the director of environmental services.

The infection control practitioner collects and analyzes surveillance data, monitors patient care practices, and participates in epidemiologic investigations. Daily review of charts of patients with fever or positive microbiology cultures allows the infection control practitioner to recognize problems with HAIs and to detect outbreaks as early as possible. The infection control practitioner is also responsible for the education of health care providers in techniques such as hand washing, processing environmental surfaces, and isolation precautions, all of which collectively minimize the acquisition and spread of infections.

It is the infection control practitioner's job to identify all cases of an outbreak. The investigation of the cluster of cases during an outbreak involves its characterization in terms of commonalities, such as location in the facility (e.g., nursery, intensive care unit); identifying or excluding the role of a specific caregiver; and prior respiratory or physical therapy. Risk factors—including underlying diseases, current or prior antimicrobial therapy, and placement of a urinary catheter—are also assessed. This information helps the infection control committee determine the reservoir of the organism in the facility—that is, the place where it exists and how the organism is transmitted from its reservoir to the patient.

Microorganisms are spread in health care facilities through several modes:

- Direct contact—for example, in contaminated food or intravenous solutions
- Indirect contact—for example, from patient to patient on the hands of HCWs (MRSA, rotavirus)
- Droplet contact—for example, inhalation of droplets (>5 μm in diameter) that cannot travel more than 3 feet (pertussis)
- Airborne contact—for example, inhalation of droplets (>5 μm) that can travel large distances on air currents (tuberculosis)
- Vector-borne contact—for example, disease spread by vectors, such as mosquitoes (malaria) or rats (rat-bite fever); this mode of transmission is rare in hospitals within developed countries

Once the reservoir is known, the infection control practitioner can implement control measures, such as reeducation regarding hand washing (in the case of spread by HCWs) or hyperchlorination of air-conditioning cooling towers such as in the case of legionellosis (caused by the bacterium *Legionella pneumophila*).

Role of the Microbiology Laboratory

The microbiology laboratory supplies the data on organism identification and antimicrobial susceptibility profiles that the infection control practitioner reviews daily for evidence of HAI. Thus, the laboratory personnel must be able to detect potential microbial pathogens and then accurately identify them to species level and perform appropriate susceptibility testing. The microbiology laboratory staff should also monitor multidrug-resistant organisms by tabulating data on antimicrobial susceptibilities of common isolates and studying trends indicating emerging resistance. Significant or abnormal findings or trends in susceptibility profiles of isolates should be immediately reported to the infection control practitioner. If an outbreak is suspected, the laboratory works in tandem with the infection control committee by (1) saving all isolates, (2) culturing possible reservoirs (patients, personnel, or the environment), and (3) performing typing of strains to establish relatedness between isolates of the same species. Microbiology laboratories are also obligated by law to report certain isolates or syndromes to public health authorities. It is the responsibility of the laboratory to be familiar with the reporting requirements within the service area of the laboratory.

Characterizing Strains Involved in an Outbreak

The ideal system for typing microbial strains involved in outbreaks should be standardized, reproducible, sensitive, stable, readily available, inexpensive, applicable to a wide range of microorganisms, and field tested in other epidemiologic investigations. Standardization of methods is important so that results from one institution can be compared with those from another, facilitating a larger investigation if deemed necessary. Although no such perfect system is currently available, several methods are used to aid in typing epidemic strains. There are two major ways to type strains using either phenotypic traits or molecular typing methods.

Classic phenotypic techniques include biotyping (analyzing unique biologic or biochemical characteristics), the use of antibiograms (analyzing antimicrobial susceptibility patterns), and serotyping (serologic typing of bacterial or viral antigens, such as bacterial cell wall [O] antigens). Bacteriocin typing, which examines an organism's susceptibility to bacterial peptides (proteins), and bacteriophage typing, which examines the ability of bacteriophages (viruses capable of infecting and lysing bacterial cells) to attack certain bacterial strains, have been useful for typing *Pseudomonas aeruginosa* and *S. aureus,* respectively; these techniques, however, are not widely available.

Genotypic, or molecular, methods have largely replaced phenotypic methods as a means of confirming the relatedness of strains involved in an outbreak. Plasmid analysis and restriction endonuclease analysis of chromosomal DNA are widely used. Plasmids are extrachromosomal pieces of genetic material (nucleic acids) that self-replicate (reproduce) in tandem with the bacterial genome and are passed to newly replicated organisms during cell division. Plasmids may also be transferred from one bacterial cell to another by conjugation or transduction (Chapter 2). Plasmid analysis has often been used to explain the occurrence of unusual or multiple-antibiotic resistance patterns. It has been shown that plasmids or R factors (resistance genes carried on plasmids) can facilitate outbreaks when a specific plasmid is transmitted from one genus of bacteria to another. Plasmid profiles, patterns created when plasmids are separated based on molecular weight by agarose gel electrophoresis, can also be used to characterize the similarity of bacterial strains. Relatedness of strains is based on the number and size of plasmids, with strains from identical sources showing identical plasmid profiles. Plasmids themselves or chromosomal deoxyribonucleic acid (DNA) may also be typed by means of restriction endonuclease digestion patterns. Restriction enzymes recognize specific nucleotide sequences in DNA and produce double-stranded cleavages that break the DNA into smaller fragments. The fragments of various sizes are separated using gel electrophoresis based on molecular weight. The specific recognition sequence and cleavage site have been defined for a great many of these enzymes. Modifications of the basic restriction endonuclease technique have been developed to reduce the number of bands generated to fewer than 20 to make the gels easier to interpret. These include pulsed-field gel electrophoresis (PFGE) and hybridization of ribosomal ribonucleic acid (RNA) with short fragments of DNA. Plasmid restriction digests have been used to type *S. aureus* and coagulase-negative staphylococci, and PFGE is the preferred method for typing enterococci, enteric gram-negative rods, and other gram-negative rods.

Other molecular methods, such as polymerase chain reaction (PCR), are used in conjunction with these methods for strain typing. In addition to strain typing, susceptibility to some antibiotics can be predicted by PCR and sequencing of specific genetic loci within the bacterial genome. Advances in next generation sequencing (NGS), which allows a laboratory to sequence an entire microorganism genome in less than an hour, has the potential to revolutionize epidemiological studies. This will undoubtedly improve the speed associated with the identification of antibiotic-resistant bacterial infections or confirm results observed in culture-based assays.

Molecular methods (nucleic acid–based tests) are discussed in more detail in Chapter 8.

Preventing Health Care–Associated Infections

The CDC published guidelines in the 1970s specifying isolation precautions in hospitals. Techniques for isolation precautions included (1) HCWs washing their hands between caring for different patients; (2) isolation of infected patients in private rooms or placing patients with the same clinical syndrome in semiprivate rooms if private rooms are not available; (3) wearing of masks, gowns, and gloves when caring for infected patients; (4) bagging of contaminated articles, such as bed linens, before removing them from the room; (5) processing of all isolation rooms after the patient is discharged; and (6) placement of cards on the patient's door specifying the type of isolation and instructions for visitors and HCWs. Categories of isolation were also established that included (1) strict isolation for highly contagious diseases such as chickenpox, pneumonic plague, and Lassa fever; (2) respiratory isolation for diseases such as measles, *H. influenzae,* or *Neisseria meningitidis;* (3) enteric precautions for diseases such as amoebic dysentery, *Salmonella,* and *Shigella;* (4) contact isolation for patients infected with multidrug-resistant bacteria; (5) acid-fast bacilli (AFB) isolation for persons suspected of having a *Mycobacterium tuberculosis* infection; (6) drainage and secretion precautions for persons with conjunctivitis and burns; and (7) blood and body fluid precautions for individuals with acquired immune deficiency syndrome (AIDS). Over time, a system of disease-specific precautions was added to the category-specific ones, and hospitals were given the option of using one of the two systems. Disease-specific precautions were more cost-effective, in that only those precautions specifically necessary were used to interrupt the transmission of a single disease.

In 1996, the CDC developed a new system of standard precautions synthesizing the features of universal precautions (Chapter 4) and body substance isolation. Standard precautions are used in the care of all patients and apply to blood; all body fluids, secretions, and excretions except sweat, regardless of whether they contain visible blood; nonintact skin; and mucous membranes.

• BOX 78.1 Infection Control Measures for Standard Precautions

- Health care workers (HCWs) should wash hands frequently using a plain soap except in special circumstances—for example, preoperatively or after handling dressings from patients on contact isolation.
- HCWs should wear gloves when touching blood, body fluids, secretions, excretions, and contaminated items.
- HCWs should wear a mask, gown, eye protection, or face shield as appropriate.
- Each hospital should ensure that it has adequate procedures for routine care, cleaning, and disinfection of environmental surfaces, beds, bed rails, and bedside equipment.
- Hospitals should handle, transport, and launder used linen soiled with blood, body fluids, secretions, and excretions in a manner that prevents skin and mucous membrane exposure and contamination of clothing, and that prevents the transfer of microorganisms to other patients or the environment.
- HCWs should take care to prevent injuries when using needles, scalpels, and other sharp instruments or devices.
- HCWs should use equipment, such as mouthpieces and resuscitation bags, instead of mouth-to-mouth resuscitation.
- HCWs should refrain from handling patient care equipment if they have exudative lesions or weeping dermatitis.
- Hospitals should place incontinent or nonhygienic patients in a private room.
- Hospitals should ensure that reusable equipment is properly sterilized.
- Hospitals should ensure that single-use items are discarded properly.

Modified from Healthcare Infection Control Practices Advisory Committee (HICPAC), 2007.

In addition, transmission-based precautions are used for patients known (or suspected) to be infected with pathogens spread by airborne or droplet transmission or by contact with dry skin or fomites. Box 78.1 lists infection control measures for standard precautions. Table 78.1 lists the infectious agents or syndromes along with the respective infection control measures for each transmission-based precaution. Many infection control practitioners find these guidelines substantially less cumbersome to implement than the old category- and disease-specific measures. Health care facilities, however, may modify these guidelines to fit their individual situations as long as their number of HAIs remains low.

Some of the potential agents of bioterrorism can be transmitted person to person (smallpox, pneumonic plague, and viral hemorrhagic fevers including Ebola) and some cannot (anthrax). The ones that can be easily transmitted have specific transmission-based precautions—that is, airborne precautions for smallpox, droplet precautions for patients with pneumonic plague, and contact precautions for individuals with one of the viral hemorrhagic fevers (Ebola, Marburg, and others).

Surveillance Methods

Most routine environmental cultures in a health care facility are now considered to be of little use and should not be performed unless there are specific epidemiologic implications. The decision to perform these cultures should be determined by the infection control team. However, certain surveillance cultures are still performed as a method of limiting outbreaks. These include culturing cooling towers or hot water sources for *Legionella* spp.; culturing water and dialysis fluids; endotoxin testing; culturing blood bank products, especially platelets; and surveillance cultures for VRE, MRSA or oxacillin-resistant *S. aureus*, and VRSA using rectal and oropharyngeal swabs. Physical rehabilitation centers often culture hydrotherapy equipment (whirlpools) quarterly to verify that cleaning methods are adequate; some centers perform such routine cultures more frequently.

Routine surveillance of air handlers, food utensils, food equipment surfaces, and respiratory therapy equipment is no longer recommended; neither is monitoring infant formulas prepared in-house nor items purchased as sterile. A better approach is for the infection control team to monitor patients for the development of an HAI that might be related to the use of contaminated commercial products. In the event of an outbreak or an incident related to suspected contamination, a microbiologic study would be indicated. However, most often, such infections are caused by in-use contamination, rather than contamination during the manufacturing process. Suspect lots of fluid and catheter trays should be saved, and the US Food and Drug Administration (FDA) should be notified if contamination of an unopened product is suspected.

Although some institutions still require preemployment stool cultures and ova and parasite examinations on food handlers, most now recognize that this is of limited value. It is much more important for food handlers to submit specimens for these tests if they develop diarrhea. Similarly, most hospitals no longer screen personnel routinely for nasal carriage of *S. aureus.* Although a significant percentage of the general population, including hospital personnel, are known to carry this organism, most individuals rarely shed enough organism to pose a hazard, and there is no simple way to predict which nasal carriers will disseminate staphylococci.

All steam and dry-heat sterilizers and ethylene oxide gas sterilizers should be checked at least once weekly with a liquid spore suspension test vial to verify complete sterilization.

Health care facilities that perform bone marrow transplantation or treat hematologic malignancies may also conduct surveillance cultures of severely immunocompromised patients who occupy laminar flow rooms. In these instances, the isolation of specific organisms may have predictive value for subsequent systemic infection. Air sampling for fungi during construction is also indicated, especially if patients

TABLE 78.1 **Transmission-Based Precautions**

Type of Precaution	Specific Etiologic Agents or Syndromes	Infection Control Measures
Airborne	Measles Varicella Tuberculosis Smallpox	Place patient in private room that has monitored negative air pressure, 6–12 air changes per hour, and appropriate discharge of air outdoors or monitored HEPA filtration of room air before air is circulated to other areas of the hospital or cohorting of patients—that is, placing patients with the same infection in the same room, if private rooms are not available. Health care workers (HCWs) should wear respiratory protection when entering rooms of patients with known or suspected tuberculosis and, if not immune, for patients with measles or varicella as well. Transport patients out of their room only after placement of a surgical mask.
Droplet	Invasive *Haemophilus influenzae* type b infection, including meningitis, pneumonia, epiglottitis, and sepsis Invasive *Neisseria meningitidis* infection, including meningitis, pneumonia, and sepsis Diphtheria (pharyngeal) *Mycoplasma pneumoniae* Pertussis Pneumonic plague Streptococcal pharyngitis, pneumonia, or scarlet fever in infants and young children Adenovirus, influenza virus Mumps Parvovirus B19 Rubella	Place patient in private room without special air handling or ventilation or cohort patients. HCWs should wear mask when working within 3 feet of patient. Transfer patients out of their room only after placement of a surgical mask.
Contact	Gastrointestinal, respiratory, skin, or wound infections, or colonization with multidrug-resistant bacteria *Clostridiodes difficile* For diapered or incontinent patients: *Escherichia coli* O157:H7, *Shigella*, hepatitis A virus, or rotavirus Respiratory syncytial virus, parainfluenza virus, and enterovirus infections in infants and young children Skin infections such as diphtheria (cutaneous), herpes simplex virus (neonatal or mucocutaneous), impetigo, major abscesses, cellulitis, or decubiti, pediculosis (lice infestation), scabies (mite infestation), staphylococci furunculosis (boils) in infants and young children, zoster (disseminated or in the immunocompromised host) Viral hemorrhagic infections (Ebola, Lassa, or Marburg)	Place patient in a private room without special air handling or ventilation or cohort patients. HCWs should wear gloves when entering the patient's room. HCWs should wash hands with a special antimicrobial agent or a waterless antiseptic agent. HCWs should wear a mask and eye protection during activities that are likely to generate splashes of blood, body fluids, secretions, or excretions. HCWs should wear a gown during procedures likely to generate splashes. HCWs should ensure reusable equipment is properly sterilized. HCWs should ensure that single-use items are properly discarded.

Modified from Healthcare Infection Control Practices Advisory Committee (HICPAC), 2007.

are immunocompromised and are being treated near the construction site.

The US Pharmacopeia published requirements for monitoring of sterile compounding in hospital pharmacies. The laminar flow hoods, biologic safety cabinets, clean rooms, and donning areas must be monitored weekly or monthly so that intravenous or intrathecal products and drugs used in the operating room are made (compounded) under sterile conditions.

Chapter Review

1. How do HAIs differ from community-acquired infections?
   - **a.** HAIs are acquired after patients are admitted to the medical facility.
   - **b.** HAIs are contracted outside of a health care setting.
   - **c.** HAIs are present on admission.
   - **d.** Organisms of HAI are usually more antibiotic sensitive.
2. Which of the following factors could determine the likelihood that a given patient would acquire a health care–associated infection?
   - **a.** Susceptibility of the patient to the infection
   - **b.** The virulence of the infecting organism
   - **c.** The nature of the patient's exposure to the infecting organism
   - **d.** All the above
3. What is the most common type of health care–associated infection?
   - **a.** Urinary tract infection
   - **b.** Pneumonia
   - **c.** Surgical site infection
   - **d.** Bloodstream infection
4. The emergence of antibiotic-resistant microorganisms can be mainly attributed to:
   - **a.** The size of the medical facility
   - **b.** The use and overuse of antibiotics
   - **c.** The patient's blood type
   - **d.** Geographic location
5. Within an infection control committee, who is primarily responsible for collecting and analyzing surveillance data, monitoring patient care practices, and participating in epidemiologic investigations?
   - **a.** The microbiologist
   - **b.** The infection control practitioner
   - **c.** The epidemiologist
   - **d.** The pharmacist
6. The spread of MRSA from patient to patient on the hands of HCWs is an example of which mode of transmission for microorganisms?
   - **a.** Airborne contact
   - **b.** Direct contact
   - **c.** Indirect contact
   - **d.** Vector-borne contact
7. In the event of an infectious outbreak, the microbiology laboratory works in tandem with the infection control committee by fulfilling all the following duties *except:*
   - **a.** Saving all isolates
   - **b.** Culturing possible reservoirs (patients, personnel, or the environment)
   - **c.** Performing typing of strains to establish relatedness between isolates of the same species
   - **d.** Monitoring the number of missed days by employees because of sickness
8. In characterizing strains involved in an outbreak, what are the two major ways to type strains?
   - **a.** Classic phenotypic techniques
   - **b.** Molecular typing methods
   - **c.** Both A and B
   - **d.** None of the above
9. Many isolation techniques can be implemented in a health care facility; however, which of the following techniques remains the cornerstone of the modern infection control programs?
   - **a.** HCWs washing hands between patients
   - **b.** Segregation of infected patients in private rooms
   - **c.** Wearing of masks, gowns, and gloves when caring for infected patients
   - **d.** Bagging of contaminated articles such as bed linens
10. Which of the following statements is true about surveillance cultures?
    - **a.** Routine environmental cultures in a medical facility are now considered to be of great value.
    - **b.** Certain surveillance cultures are still performed as a method of limiting outbreaks, such as culturing cooling towers or hot water sources for *Legionella* spp.
    - **c.** Routine surveillance of air handlers, food utensils, and food equipment surfaces is strongly recommended.
    - **d.** Preemployment stool cultures and ova and parasite examinations on all food handlers should be a requirement.

79

Sentinel Laboratory Response to Bioterrorism

OBJECTIVES

1. Define and give examples of a bio crime.
2. Distinguish between covert and overt assaults.
3. Define and give examples of select agents.
4. Site two laws that govern the possession of select agents.
5. List the government agencies that must be notified, by registration, before a laboratory may possess a select agent.
6. State the components of a biosecurity plan.
7. Summarize the standard operating procedures required for laboratories that maintain select agents.
8. Diagram and give a brief description of the Laboratory Response Network.
9. Identify responsibility of each hierarchical level through which an agent passes in its process of being defined as an agent of bioterrorism.
10. Outline the steps microbiology laboratories must follow if a select agent is isolated from a clinical specimen.
11. Explain the requirements for operation as a sentinel laboratory.
12. Name the government agencies responsible for the investigation and management of a bioterrorism event.
13. Given microbiologic characteristics, identify the most likely suspect agent of terror.

General Considerations

Bioterrorism may have started centuries ago; however, lack of proper documentation made it difficult for historians and microbiologists to differentiate natural epidemics from alleged biological attacks. The practice of clinical microbiology changed significantly after *Bacillus anthracis* was intentionally released into the United States postal system in October 2001. Before this release there were a few events in which microorganisms were used to intentionally harm the civilian population in the United States.

The first incident, in 1984, was a large community outbreak of salmonellosis caused by the intentional contamination of restaurant salad bars in The Dalles, Oregon. In this incident, a cult leader, Baghwan Sri Rajneesh, set out to influence the outcome of a local election by incapacitating voters. Cultures of *Salmonella enterica* serotype Typhi were grown at a laboratory within the cult's compound. Ultimately, 751 individuals fell ill; luckily there were no deaths. Another religious cult, Aum Shinrikyo, known for the famous sarin gas attack in Tokyo in 1995, was developing biological weapons using *Clostridium botulinum* and *B. anthracis,* but with no proof of effectiveness. In 1996, an outbreak among laboratory workers took place and was caused by a microbiology technologist in Dallas, Texas, purposely contaminating muffins and donuts with *Shigella dysenteriae* type 2. Forty-five laboratory workers developed gastroenteritis; four individuals were hospitalized.

The event in October 2001 stunned the country. Although there had previously been sporadic instances of suspicious letters, those events proved to be hoaxes. This outbreak resulted from the delivery of weaponized anthrax spores in mailed letters or packages; ultimately there were 11 cases of inhalational anthrax and 11 of cutaneous disease. Five individuals died. The attacks prompted institutions to implement or modify bioterrorism readiness plans. The US government also reviewed the public health response and identified areas for improvement.

Bio Crime

A bioterrorism event, also known as a **bio crime,** is an intentional assault on a person, or group of people, using a pathogen or toxin. The assault may be overt or covert. An overt attack is announced. The letters sent to Senators Daschle and Leahy in 2001 are examples of an overt event; a note inside each envelope announced that the individual opening it had been exposed to *B. anthracis* spores. A covert attack is unannounced; the recipient receives no indication that a threat is present. The package sent to the journalist at American Media, Inc., is an example of a covert event; an environmental investigation of his office uncovered the anthrax spores after his death and the illness of a coworker.

Government Laws and Regulations

The bombings at the World Trade Center in 1993 and the federal building in Oklahoma City in 1995 led Congress to pass the Antiterrorism and Effective Death Penalty Act of 1996. Section 511 (d) restricts the possession and use of materials capable of producing catastrophic damage in the hands of terrorists by requiring their registration. A companion law, the Uniting and Strengthening America by Providing Appropriate Tools Required to Intercept and Obstruct Terrorism (USA PATRIOT) Act of 2001, prohibits any person to knowingly possess any biologic agent, toxin, or delivery system of a type or in a quantity that, under the circumstances, is not reasonably justified by prophylactic, protective, bona fide research, or other peaceful purpose. Later, the Public Health Security and Bioterrorism Preparedness and Response Act of 2002 required institutions to notify the Department of Health and Human Services (DHHS) or the United States Department of Agriculture (USDA) of the possession of specific pathogens or toxins called **select agents**. Therefore, clinical laboratories possessing any select agents must register with the Centers for Disease Control and Prevention (CDC), a branch of the DHHS. Violation of any of these statutes carries criminal penalties. The pathogens and toxins classified as select agents are listed in Box 79.1. The list is updated as needed.

Bioterrorism agents are divided into three categories: A, B, or C. **Category A agents** are considered those presenting the highest risk to public health and national security, because they are easily disseminated or transmitted from person to person and have high mortality rates. Category A includes pathogens such as *B. anthracis* and *Yersinia pestis.* **Category B agents** are moderately easy to disseminate and have moderate to low mortality rates. This category includes *Brucella* spp. and *Clostridium perfringens* toxin. **Category C** contains emerging pathogens that could be engineered for mass spread in the future. Additional information may be found in Appendix F of the fifth edition of the CDC and the National Institutes of Health (NIH) manual *Biosafety in Microbiological and Biomedical Laboratories* (BMBL). The publication contains national guidelines to promote the safety and health of workers in biological and medical laboratories.

Biosecurity

Biosecurity is the latest issue of concern for microbiology laboratory directors and managers. Laboratories must conduct a risk assessment and threat analysis to write a security plan. This plan must include physical security (e.g., electronic card key access and locked freezers and refrigerators), and data system (laboratory information system) security and security policies for personnel.

Most hospital clinical laboratories have decided not to store any select agents. Some commercial laboratories, on the other hand, store select agents for use as positive controls for comparison with suspect samples. These laboratories must write standard operating procedures (SOPs) for (1) the access of select agents; (2) specimen accountability; (3) the receipt of select agents into the laboratory; (4) the transfer or shipping of select agents from the laboratory; (5) the reporting of incidents, injuries, and breaches of security; and (6) an emergency response plan if security is breached or the isolate is unintentionally released during an accident. They must also register the agents with the CDC.

• BOX 79.1 List of Select Agents[a]

Viruses

Crimean-Congo hemorrhagic fever virus
Eastern equine encephalitis virus
Ebola viruses
Hendra virus
Herpesvirus 1 (Herpes B virus)
Lassa fever virus
Marburg virus
Monkeypox virus
Nipah virus
Reconstructed 1918 influenza virus
Rift Valley fever virus
South American hemorrhagic fever viruses (Junin, Machupo, Sabia, Flexal, Guanarito)
Tick-borne encephalitis complex viruses
Variola major virus (smallpox virus)
Variola minor virus (Alastrim)
Venezuelan equine encephalitis virus

Bacteria

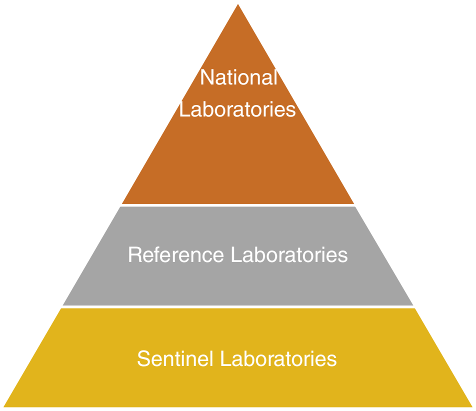
Bacillus anthracis
Brucella abortus, Brucella melitensis, Brucella suis
Burkholderia (Pseudomonas) mallei
Burkholderia (Pseudomonas) pseudomallei
Clostridium botulinum
Francisella tularensis
Yersinia pestis
Rickettsiae
Coxiella burnetii
Rickettsia prowazekii
Rickettsia rickettsii

Toxins

Abrin
Botulinum toxins
Clostridium perfringens epsilon toxin
Conotoxins
Diacetoxyscirpenol
Ricin
Saxitoxin
Shiga-like ribosome inactivating proteins
Shigatoxin
Staphylococcal enterotoxins
T-2 toxin
Tetrodotoxin

[a] HHS and USDA Select Agents and Toxins, 7 CFR Part 331, 9 CFR Part 121, and 42 CFR Part 73.

Each clinical laboratory should have a bioterrorism response plan. The plan should include policies and procedures to be enacted when a suspicious isolate cannot be ruled out as a biothreat agent. If a laboratory has any questions about isolating, identifying, or submitting an organism that may be an agent of bioterrorism, laboratory personnel should call the state public health laboratory. The select agent must be either sent to a public health laboratory or destroyed within 7 days of identification. If the agent is autoclaved, its destruction must be documented using Animal and Plant Health Inspection Service (APHIS)/CDC Form 4, available at https://www.selectagents.gov/forms.html.



• **Fig. 79.1** Laboratory network for biologic terrorism.

Laboratory Response Network

Laboratory testing and communication between clinical and public health laboratories are critical when responding to a bioterrorism event. To address this issue, the CDC, in partnership with the Association of Public Health Laboratories and the Federal Bureau of Investigation (FBI), established the **Laboratory Response Network (LRN).** The LRN is a three-tier system. **Sentinel (formerly level A) laboratories** receive patient samples, rule out pathogens, and transfer suspicious specimens to reference laboratories. According to the CDC, the LRN works with the American Society for Microbiology (ASM) and state public health laboratory directors to ensure that private and commercial laboratories are part of the LRN. There are an estimated 2500 private and commercial laboratories serving in the sentinel capacity in the United States. Most of these laboratories are hospital-based clinical institutions and commercial diagnostic laboratories. **Reference laboratories** possess the required reagents and technology to perform confirmatory testing on pathogens. According to the CDC, reference laboratories are made up of more than 150 state and local public health, military, international, veterinary, agriculture, food, and water testing laboratories. In addition to laboratories in the United States, facilities located in Australia, Canada, the United Kingdom, Mexico, and South Korea serve as reference laboratories abroad. Confirmed bioterrorism agents are sent to a national laboratory. **National laboratories,** such as those at the CDC, US Army Medical Research Institute for Infectious Diseases, or the Naval Medical Research Center, are responsible for the definitive characterization of agents (Fig. 79.1).

Role of the Sentinel Laboratory

The main role of sentinel microbiology laboratories is to determine whether a targeted agent is suspected in a human specimen. Detection and recognition of a possible bioterrorism event depend on the following:

- A laboratory having an active microbial surveillance and monitoring program
- Vigilant technologists looking for a disease that (1) does not occur naturally in a geographic region (e.g., plague in New York City); (2) is transmitted by an aerosol route of infection; and (3) is a single case of disease caused by an unusual agent (e.g., *Burkholderia mallei*)
- Good communication with infection control practitioners, infectious disease physicians, and local or regional public health laboratories

TABLE 79.1 **Algorithm for Sentinel Laboratories for Likely Bioterrorism Agents**[a]

Agent	Sentinel Laboratory Procedures	Comments
Bacillus anthracis	Colony: large, nonhemolytic, stands up like a beaten egg (Fig. 79.2) Gram stain: large, gram-positive rods (Fig. 79.3) Catalase: positive Motility: nonmotile Optional: use of the Red Line Alert Test (Tetracore, Inc.), cleared by the Food and Drug Administration, to rule out *B. anthracis* (see Chapter 15 for a more complete discussion of this test)	May be mistaken for *Bacillus megaterium*
Brucella spp.	Colony: small, nonhemolytic Gram stain: lightly staining tiny gram-negative coccobacilli Oxidase: positive Urease: positive Motility: nonmotile	May be mistaken for *Haemophilus* or *Francisella*
Francisella tularensis	Colony: pinpoint growth after 48 h Gram stain: pleomorphic, minute, faintly staining gram-negative coccobacilli Oxidase: negative Urease: negative Beta-lactamase: positive	May be mistaken for *Haemophilus* or *Actinobacillus*

Continued

TABLE 79.1 **Algorithm for Sentinel Laboratories for Likely Bioterrorism Agents[a]—cont'd**

Agent	Sentinel Laboratory Procedures	Comments
Yersinia pestis	Colony: pinpoint growth on blood agar after 24 h Gram stain: gram-negative rods exhibiting bipolar staining Catalase: positive Oxidase: negative Urease: negative Indole: negative	Rapid systems may misidentify as *Shigella* spp., H2S-negative *Salmonella* spp., *Acinetobacter* spp., and *Yersinia pseudotuberculosis*
Clostridium botulinum	None	Send all specimens to reference laboratory; patient must get antitoxin immediately
Smallpox and hemorrhagic fever viruses	None	Smallpox can be mistaken for herpes virus if inoculated into routine tissue culture cells

[a] See individual chapters for a more detailed discussion of each organism.

• **Fig. 79.3** Gram stain of *Bacillus anthracis*.

Sentinel laboratories must have a class II biologic safety cabinet, have copies of level A protocols containing the algorithms for ruling out suspicious microorganisms (Table 79.1), and participate in an applicable proficiency testing program such as the College of American Pathologist's Laboratory Preparedness Survey. Because sentinel laboratories rule out and refer microorganisms, proper knowledge of appropriate packaging and shipping is critical (Chapter 4); all specimens must be classified as infectious. Sentinel laboratories should never accept nonhuman specimens such as those from animals or the environment. Such specimens should be submitted directly to the nearest reference laboratory.

Rapid communication between LRN sentinel members and their reference public health laboratories is essential. Each sentinel laboratory must know how to contact public health officials 24 hours/day. Sentinel laboratories, however, do not make the determination that a bioterrorist event has occurred and do not notify law enforcement. The FBI has primary responsibility when a bioterrorism event occurs as outlined in Presidential Decision Directive 39. A bioterrorist event is first and foremost a criminal investigation. The Federal Emergency Management Agency (FEMA) has the lead role in consequence management. FEMA receives assistance from the Department of Defense (DOD), Department of Energy (DOE), USDA, Department of Transportation (DOT), DHHS, and Environmental Protection Agency (EPA). FEMA, for example, calls for the deployment of the National Pharmaceutical Stockpile by the CDC so victims may be appropriately treated. Early recognition is the key to saving lives, and sentinel laboratorians are on the front lines in the fight against bioterrorism.

Because sentinel laboratories are charged with ruling out possible bioterrorism agents and referring suspicious isolates to reference laboratories for confirmatory testing, each sentinel laboratory's bioterrorism response plan must include a telephone number and contact information for the reference laboratory.

• BOX 79.2 Infectious Agents, Toxins, and Procedures for Which Sentinel Level Clinical Microbiology Laboratory Guidelines Are Provided[a]

Anthrax *(Bacillus anthracis)*
Brucella spp.
Botulinum toxin
BT readiness plan
Burkholderia spp.

• Fig. 79.4 Algorithm for the differentiation of bioterrorism agents.

A sentinel laboratory's key responsibility is to be familiar with likely agents involved in a bio crime; it must have SOPs to accomplish this task. To standardize the process nationwide, ASM has compiled a series of guidelines entitled "Sentinel level clinical laboratory guidelines for suspected agents of bioterrorism and emerging infectious diseases." Guidelines for individual bacteria listed in Box 79.2 may be accessed on the ASM website at https://www.asm.org/index.php/science-skills-in-the-lab/sentinel-guidelines. Algorithms for the identification of likely bioterrorism agents are provided in Table 79.1 and Fig. 79.4.

Visit the Evolve site for a complete list of procedures, review questions, and case studies.

CASE STUDY 79.1

From October 4 to November 2, 2001, the first 10 confirmed cases of inhalational anthrax caused by intentional release of *B. anthracis* were identified in the United States. Epidemiologic investigation indicated that the outbreak, in the District of Columbia, Florida, New Jersey, and New York, resulted from intentional delivery of *B. anthracis* spores through mailed letters or packages. This case study describes the clinical presentation and course of these cases of bioterrorism-related inhalational anthrax. The median age of patients was 56 years (range 43–73 years), 70% were male, and except for one, all were known or believed to have processed, handled, or received letters containing *B. anthracis* spores. The median incubation period from the time of exposure to onset of symptoms, when known ($n = 6$), was 4 days (range 4–6 days). Symptoms at initial presentation included fever or chills ($n = 10$), sweats ($n = 7$), fatigue or malaise ($n = 10$), minimal or nonproductive cough ($n = 9$), dyspnea ($n = 8$), and nausea or vomiting ($n = 9$). The median white blood cell count was $9.8 \times 10^3/\text{mm}^3$ (range 7.5–13.3), often with increased neutrophils and band forms. Nine patients had elevated serum transaminase levels, and six were hypoxic. All 10 patients had abnormal chest x-rays; abnormalities included infiltrates ($n = 7$), pleural effusion ($n = 8$), and mediastinal widening ($n = 7$). Computed tomography of the chest was performed on eight patients, and mediastinal lymphadenopathy was present in seven. With multidrug antibiotic regimens and supportive care, survival of patients (60%) was markedly higher (<15%) than previously reported.

From Jernigan JA, Stephens DS, Ashford DA, et al. Bioterrorism-related inhalational anthrax: the first 10 cases reported in the United States. *Emerg Infect Dis* 2001;7:933–944.

Questions

1. What were the major symptoms evident upon clinical presentation of the inhalational anthrax patients?
2. What were the major laboratory results that contributed to the diagnosis of inhalational anthrax?
3. What general treatment strategy was used in the care of these patients that ultimately provided a markedly higher survival percentage than had been previously reported?

Chapter Review

1. Microbiology laboratories possessing pathogens classified as select agents must register with what organization?
- **a.** FBI
- **b.** DOT
- **c.** FEMA
- **d.** CDC

2. What type of laboratory performs definitive characterization of select agents?
- **a.** Level A
- **b.** Reference
- **c.** National
- **d.** Sentinel

3. Sentinel laboratories are required to have:
- **a.** A class II biologic safety cabinet
- **b.** Reagents to perform confirmatory testing of suspicious pathogens
- **c.** SOPs for accepting environmental samples
- **d.** Contact information for the FBI

4. Microbiology laboratory operating procedures for select agents have been standardized by what organization?
- **a.** FEMA
- **b.** ASM
- **c.** DOE
- **d.** EPA

5. The detection of possible biothreat agents in patient samples is primarily the responsibility of the:
- **a.** Reference laboratory
- **b.** National laboratory
- **c.** CDC
- **d.** Sentinel laboratory

6. True or False

_____If weaponized anthrax spores are delivered through the United States postal system, it is an example of a bio crime.

_____ *Y. pestis* is a select agent.

_____A biosecurity plan contains algorithms for identification of *C. botulinum.*

_____Laboratories maintaining select agents must have a standard operating procedure for shipping those agents.

_____ If a microbiology laboratory isolates a select agent from a clinical specimen, the laboratory must destroy the agent within 30 days.

7. Matching: *Match each term with the correct description.*

_____ FBI	a. communication link with sentinel laboratory
_____ College of American Pathologists (CAP)	b. lead role in bioterrorism consequence management
_____ ASM	c. primary responsibility when bioterrorism event occurs
_____ FEMA	d. provides guidelines for standard operating procedures
_____ state public health laboratory	e. provides proficiency testing surveys

Glossary

A

Abscess Localized collection of pus, a fluid in infected tissue that consists of white blood cells, bacteria, and dead tissue.

Abstriction Formation of spores in fungi by pinching off or constriction.

Accessioning Receipt of a specimen delivered to the laboratory, and the recording and assigning of a unique numerical identifier.

Accidental host A patient that becomes infected with a parasite that is not normally associated with the human as a host; a host that is not required as part of the parasitic life cycle.

Accolé forms See appliqué forms.

Accuracy Ability of a test under evaluation to match or be close to the value or the results of an accepted standard test.

Acidic dye (stain) A dye or stain that has a negative charge and binds to positively charged molecules. Generally, used for background staining in microbiology.

Acid-fast Characteristic of certain bacteria, such as mycobacteria, that involves resistance to decolorization by acids when stained by an aniline dye, such as carbolfuchsin.

Acquired immunity The body's specific response in the host to the infecting organism.

Acquired immunodeficiency syndrome (AIDS) Disease characterized by opportunistic infections and other complications that result due to immunodeficiency because of a viral infection with human immunodeficiency virus (HIV).

Acquired resistance When a microorganism that was initially susceptible to an antimicrobial agent becomes resistant to an agent by mutation or by acquisition of an antimicrobial-resistant genetic determinant.

Acridine orange A nonspecific cationic fluorescent dye that binds to all nucleic acids.

Acrodermatitis chronica atrophicans (ACA) A long-lasting, diffuse, red or bluish-red skin rash that is associated with third-state Lyme borreliosis.

Active immunization Activation of the immune system resulting in exposure to an antigen either by direct contact with the antigen in the environment or through artificial means.

Acute Occurs rapidly, generally with notable symptoms that may be severe.

Acute phase The physiological response of the human body soon after the onset of an infection or injury.

Acute sera Serum collected for antibody determination early during an illness when little or no antibody would have been produced.

Acute urethral syndrome Lower urinary tract infection that may be difficult to differentiate from cystitis.

Adiaspores Spores produced by the systemic fungus *Emmonsia* spp., which increase in size within the host but do not reproduce. These become walled or granulomatous in the lungs of the infected patient.

Aerial hyphae Fungal filaments (hyphae) that are found above the nutrient base or substrate.

Aerobe, strict or obligate Microorganism requiring the presence of ambient air, which contains 21% oxygen and a small amount of carbon dioxide (0.03%). Cannot live or grow in the absence of oxygen, or anaerobically.

Aerobic respiration The process of generating energy (adenosine triphosphate) with oxygen as the final electron receptor.

Aerosol Atomized particles suspended in air; in context of this textbook, microorganism suspended in air.

Aerotolerance test Culture that is used to identify a true anaerobe. A blood agar plate is inoculated and placed in an anaerobic environment; two chocolate plates are inoculated, and one is placed in a CO_2 incubator. Growth only on the blood agar and no growth on chocolate indicates that the organism is a true anaerobe.

Aerotolerant Anaerobes that do not use oxygen but are not killed by a small amount (5% O_2).

Affinity The strength of the binding of a single antigen-binding site on the antibody to the specific antigen.

Agar The most common solidifying agent used for microbiological media; it comes from the cell walls of Phaeophyta (brown algae), has the unique property of melting at high temperatures (≥95°C), and solidifies after the temperature falls below 50°C.

Agar dilution (antibiotic susceptibility testing) Agar plates containing a single antibiotic dilution used to determine antimicrobial susceptibility. Series of plates with doubling dilutions must include a plate without antibiotic for a growth control.

Agarose gel electrophoresis Separation of proteins based on molecular weight by electrical current–stimulated movement through a semisolid gel matrix.

Agglutination Aggregation or clumping of particles, such as bacteria when exposed to a specific antibody.

Alcohols (chemical disinfectant or antiseptic) 60% to 90% ethyl or isopropyl alcohol may be used as a chemical disinfectant on inanimate objects or an antiseptic on living tissue.

Aldehydes (chemical disinfectant) Formaldehyde, glutaraldehyde, and ortho-phthalaldehyde (OPA) used on surfaces such as floors. All but OPA require activation and produce strong fumes. OPA is sporicidal (kills endospores).

Aleurioconidia Hyphae where a cross wall divides the hyphae and the terminal cell differentiates into a spore.

Alopecia A medical condition that results in the loss of hair in patches or spots.

Amastigote A life cycle stage in some protozoans that is nonmotile and has no external flagella or cilia.

Ameboma Inflammatory granulomatous lesion because of amebic colitis in the bowel.

American Type Culture Collection (ATCC) Nonprofit organization that manages the commercial collection, storage, and distribution of microorganisms including fungi and bacteria as well as cell cultures for research and clinical diagnostics.

Amies medium Transport medium, with or without charcoal, that is a modification of Stuart medium (glycerol phosphate is replaced with an inorganic phosphate buffer) used for maintaining the viability of microorganisms.

Aminoglycosides Group of related antibiotics that contain an amino-modified glycoside that inhibit protein synthesis.

Amniotic Pertaining to the innermost fetal membrane forming a fluid-filled sac.

Amplicon Amplified nucleic acid product.

Anabolic (anabolism) Reactions that are synthetic in nature, generally requiring energy.

Anaerobe, strict or obligate Microorganism that grows only in complete or nearly complete absence of molecular oxygen. Atmosphere is generally composed of 5% to 10% hydrogen (H_2), 5% to 10% CO_2, 80% to 90% nitrogen (N_2), and 0% O_2.

Anaerobic respiration The process for energy generation in the absence of oxygen. Final electron acceptors may be organic or inorganic such as sulfate or nitrate.

Analyte specific reagent (ASR) Reagents, antibodies, nucleic acid probes, primers, proteins, etc., with specific properties or chemical activities provided by manufacturers for *in vitro* diagnostic use without predetermined performance characteristics. Each laboratory must determine their use and demonstrate appropriate performance characteristics. ASR is considered a medical device regulated by the US Food and Drug Administration (FDA).

Anamnestic response (secondary antibody response) More rapid production of antibodies in response to exposure to an antigen previously encountered.

Anamorph Asexual fungal form.

Anergy Absence of reaction to antigens or allergens.

Angiogenesis Forming new capillaries from preexisting ones.

Anicteric No jaundice.

Annealing The process of heating nucleic acids and then cooling to permit complementary sequences to pair during analytical processes.

Annelides Fungal organisms that form cells on the end of conidiophores or hyphae.

Annellophores Reproductive structure of a fungus that forms contiguous cells at the end.

Antagonism The interaction of two or more drugs (antimicrobials) that may interfere with or reduce the effectiveness of the treatment.

Anthroponotic A disease of humans that can be transmitted to other humans or animals.

Antibiogram A cumulative susceptibility report that tracks resistance or susceptibility of commonly isolated organisms to antimicrobials.

Antibiotic Substance produced by a microorganism that inhibits or kills other microorganisms.

Antibody (immunoglobulin) Substance (glycoprotein) formed in blood or tissues that interacts only with the antigen that induced its synthesis (e.g., agglutinin).

Antibody-mediated immunity See humoral immunity.

Antibody titer The measurement of an antibody in a serum sample. Determined by a serial dilution of the sample and expressed as the reciprocal of the highest dilution that demonstrates a positive result.

Anticoagulant Substance used to prevent clotting of specimens such as blood, bone marrow, and synovial fluid.

Anticodon A series of three nucleotides on the transfer RNA that is complementary and binds to the genetic code (triplet) on the messenger RNA.

Antigen Molecular structure that is capable of stimulating production of antibody.

Antigenic determinant See epitope.

Antigenic drift Minor changes that occur continuously over time as the virus replicates.

Antigenic shift Major changes that result in novel viral antigens.

Antimicrobial Chemical substance produced either by a microorganism or by synthetic means that is capable of killing or suppressing the growth of microorganisms.

Antimicrobial susceptibility testing (AST) Procedures used to detect *in vitro* resistance to antimicrobial agents. Procedures are based on serial dilutions or breakpoints for antimicrobials.

Antiparallel Used to describe the directionality of two molecules that are next to each other but that structurally run in opposite directions. This is used to describe the structure of DNA with a 5-prime phosphate to 3-prime hydroxyl on one strand, paired with a second strand that runs 3-prime hydroxyl to 5-prime phosphate.

Antiseptic A compound or chemical that is used on living tissue that stops or inhibits growth of microorganisms without necessarily killing them.

Antral puncture A surgical procedure used to drain or collect a specimen for diagnostic testing from the maxillary sinus.

Apical Anterior, narrowed ending of an anatomical structure of a microorganism.

Apical complex An anatomic structure that consists of cytoskeletal arrangements at the tip or narrowed end of a group of protozoans that functions to enable host cell penetration.

Apophysis Enlarged area or swelling of the sporangiophore immediately below the columella in a fungal organism.

Apoptosis Programmed cell death.

Appliqué forms (accolé forms) Trophozoite or ring stage of malaria that is attached to the outer periphery of the red blood cell; often appears like it is sitting on the outside of the cell rather than inside the cell.

Arboviruses Arthropod-borne viruses.

Arbitrary primed polymerase chain reaction (PCR) Amplification of multiple fragments within a nucleotide sequence that uses multiple short (6 to 10 nucleotides) oligonucleotide primers, not designed to amplify a specific known sequence.

Arthritis, septic Infection of synovial tissue and joint fluid of one or more joints; characterized by joint pain, stiffness, swelling, and fever.

Arthroconidium (plural Arthroconidia) Spore formed by septation of a hypha and subsequent separation of septa. Appear as square or rounded blocks.

Ascites Condition in which amounts of fluids increase and accumulate in the peritoneal cavity during infection or an inflammatory process.

Ascitic fluid Serous fluid in peritoneal cavity.

Ascocarp A large, saclike structure (fruiting body) that contains sexual spores of a fungus in the taxonomic group *Ascomycota*.

Ascospore Haploid asexual reproductive spores formed in the ascus of a fungus in the taxonomic group *Ascomycota*; usually form in groups of eight.

Aseptate Lacking septation or cellular cross walls; may also be referred to as coenocytic.

Aseptic meningitis Meningitis characterized by an increase in lymphocytes and other mononuclear cells in the cerebrospinal fluid; culture negative for most bacterial pathogens and is most often associated with viral or fungal pathogens.

Aspiration Inhalation of a fluid or solid.

Asaccharolytic Unable to break down carbohydrates.

Assimilation Utilization of nutrients. Assimilation tests are used to determine whether yeasts are able to grow with a carbohydrate or nitrate as a single source of energy; these tests are useful for biochemical identification of yeasts.

AST See antimicrobial susceptibility testing.

Atrophic rhinitis See ozena.

Auramine-rhodamine A basic dye that binds to the mycolic acid in acid-fast organisms and fluoresces at short-wave lengths.

Autochthonous Indigenous (originally occurring) inhabitant of a particular place or habitat.

Autoclave Instrument used to sterilize biohazardous trash and heat-stable objects using moist heat in the form of saturated steam under 1 atmosphere (15 pounds per square inch [psi]) of pressure with the two most common sterilization temperatures of 121°C and 132°C.

Autoinfection Infection that develops from a source within the host to another anatomical site. An example includes a parasite that is capable of migration to other areas of the body, causing damage.

Auxotroph Differing from an organism's wild type strain (prototroph) by an additional nutritional requirement that can utilize inorganic carbon sources (CO_2).

Average Nucleotide Identity (ANI) This is a comparative score between the genomic sequences of two organisms. An identity score of 95% or above is generally considered the same species, with a score below 75% as an unreliable identity between two genome sequences.

Avid The property of binding strongly, such as an antibody that strongly binds to an antigen.

Avidity Firmness of union of two substances; used commonly to describe the overall strength of binding between multiple binding sites (more than one) of an antibody to antigen.

Axial fibril Proteinaceous structure enclosed within a membrane sheath that wraps around a central core from the anterior to the posterior end of a microorganism.

Axial filament Multiple axial fibrils are the building blocks of an axial filament, which may also be referred to as an endoflagella.

Axoneme The central core of a motility organelle (cilia or flagella) in a eukaryotic microorganism; microtubule arrangement that consists of two central fibrils, surrounded by nine peripheral fibrils, referred to as a 9 + 2.

Axostyle A group of microtubules that begins at the base of a flagellum and runs the length of the body of a protozoan; may run the full length of the body and extend beyond, providing rigidity and assisting in the motility of the organism.

B

Bacillary angiomatosis Raised vascular lesions on the skin, organs, and mucous membranes associated with *Bartonella* spp. infections.

Bacille Calmette-Guérin (BCG) An attenuated strain of *Mycobacterium tuberculosis* used for immunization.

Back-up broth Supplemental or enrichment broth added to a routine culture to enhance the growth of an organism or group of organisms in the event there is no growth on the primary solid media used for isolation.

Bacteremia Presence of viable microorganisms (bacteria) in blood.

Bacterial vaginosis Noninflammatory condition in vagina characterized by foul-smelling vaginal discharge and presence of mixed bacteria.

Bactericidal Term used to describe a drug that kills microorganisms (bacteria).

Bacteriophage Virus that infects a bacterial cell.

Bacteriocins A protein that is produced by one type of bacteria that targets and kills other completing bacteria.

Bacteriostatic Term used to describe a drug that inhibits or slows the growth of a microorganism (bacteria) without killing it.

Bacterium (plural Bacteria) A single-celled prokaryotic microorganism.

Bacteriuria Presence of bacteria in urine.

Bartholinitis Inflammation of the Bartholin glands that are located posteriorly to the vagina, one on each side.

Base pair (bp) The formation of pairing of a nucleotide base on one strand of DNA, hydrogen-bonded to another nucleotide on a separate complementary strand of DNA.

Base sequence The order of nucleotides in a nucleic acid, either DNA or RNA.

Basic dye (stain) A dye or stain that has a positive charge and binds to negatively charged molecules on the outside surface of microorganisms.

Basidiospores Haploid asexual reproductive spores formed in the ascus of a fungus in the taxonomic group *Basidiomycota*; usually form in groups of four with two of each mating type.

Basidium (plural Basidia) Reproductive spore-producing structure of the fungi classified as a *Basidiomycota.*

Beta-lactamase Enzyme that is produced by a variety of microorganisms that breaks or disrupts the beta-lactam ring structure found in penicillins and/or cephalosporin.

Bifurcated Divided into two branches.

Binary fission The process of asexual reproduction, cellular division in prokaryotic cells. Cells may divide either longitudinally (along the long axis) or transversely (along the short axis), resulting in doubling of the cells.

Binomial nomenclature Naming of microorganisms that contains two names by convention, the genus followed by the species.

Biocides Chemicals that can be used to destroy all life forms are also considered sterilants. When used for shorter times, may be used as a disinfectant.

Biofilm Well-organized mono- or polymicrobial microcolonies of microorganisms enclosed in a polymer matrix of protein and polysaccharides that are separated by water channels that remove wastes and deliver nutrients.

Biologic resistance The natural (genetically determined) resistance of an organism to death or damage from a chemical or compound such as an antimicrobial.

Biological safety cabinet (BSC) An enclosure used to prevent the acquisition or spread of infection by a relatively dangerous organism. These cabinets, also called *biosafety hoods*, vary in design according to the nature of the agents (BSC 1 to 4). The enclosures maintain a negative pressure and a laminar air curtain, both of which operate to prevent escape of organisms from the interior of the hood. Air that is exhausted may be passed through a high-efficiency bacterial filter that traps microorganisms or may be passed through a furnace that incinerates the organisms.

Bioluminescence Light generation by living organisms.

Biopsy Removal of tissue for diagnostic purposes (e.g., lymph node biopsy).

Biosafety Level 1 to 4 (BSL) A specified set of practices or precautions used to prevent transmission of and infection by a microbial organism. Level 1 is considered the lowest level of precautions that can be used with microbial organisms that generally do not cause disease, all the way up to level 4, which is used for organisms considered exotic, highly contagious infectious agents that are typically fatal, and for which there are no current treatments or vaccines available to prevent infection.

Biotin Small vitamin with two binding sites, one of which can bind covalently with amine or sulfhydryl chemical groups, leaving the other free to form a strong bond with the protein avidin, which, in turn, can be bound to an enzyme. The system is used as a chemical label for nucleic acid probes, antibodies, or other molecules for *in vitro* detection.

Biotype Biologic or biochemical type of an organism. Organisms of the same biotype display identical biologic or biochemical characteristics.

Biphasic media A microbiological culture system that contains both a liquid and a solid component.

Biseriate Two layers, a mutalae and a phialide.

Blastoconidium A spore formed by budding on hyphae, pseudohyphae, or on a single cell, as in yeasts.

Bleach See hypochlorite solution.

Blepharitis Inflammation of eyelids.

Blind passage Serial passage (growth) of an infectious agent through either artificial media or an animal without any intermediate identification or characterization.

Blood-brain barrier Layer of cells between the central nervous system and the capillaries of the circulatory system that is tightly packed and selectively permeable.

B lymphocytes (B cells) Bone marrow–derived lymphocytes that, when activated (plasma cells) by specific antigens, produce antibodies in humoral immunity.

B memory cells A type of lymphocyte that results from the activation of a B lymphocyte that has been exposed to an antigen to produce protective antibodies. The parent B lymphocyte activates multiples and divides, creating more active cells known as plasma cells and other B memory cells that will remain in the body for years, to respond to a secondary challenge by the original activating antigen.

Boil An infection of the skin around a hair follicle or oil gland that appears red and swollen.

Boric acid Preservative that can be used with urine specimens for transport.

Bothrium (plural Bothria) Suction groove on the scolex of tapeworms.

Bradyzoite A slow-growing form of a microorganism that is stationary (nonmotile) within the host tissue.

Branched DNA A synthetic oligonucleotide structure that utilizes a primary probe or complementary target region that binds to the nucleic acid, with extender sequences that function to either capture a secondary target sequence that can be detected with a signal probe (amplifying the signal only) or used to then bind a set of primers, followed by amplification prior to detection.

Breakpoint Level of an antibacterial drug achievable in the serum or body fluid. Organisms inhibited by this level of drug are considered susceptible.

Bright-field microscopy See light microscopy.

Bronchial lavage Similar to bronchial washings, but this term implies instillation of a larger volume of sterile physiological buffered saline before aspiration. Alveolar organisms may be present in the lavage.

Bronchial washings Flushing of the lower respiratory tract with a sterile physiological buffered saline solution followed by aspiration from bronchial tree during bronchoscopy.

Bronchitis Inflammation of mucous membranes of bronchi caused by infectious agents or chemical irritation.

Bronchiolitis Inflammation, swelling, and narrowing of the smallest airways, bronchioles, in the lungs.

Bronchoscopy Examination of bronchi through a bronchoscope: a tubular, illuminated instrument introduced through the trachea.

Brood capsule Cyst of a tapeworm that is fluid filled, where the protoscolices (anterior heads) of the worm develop prior to being released.

BSC See biological safety cabinet.

Bubo Inflammatory enlargement of lymph node, usually in the groin, pelvic region, neck, or axilla.

Bubonic plague Most common form of disease caused by *Yersinia pestis* that results in the formation of buboes.

Buccal capsule Mouth or anterior oral opening of a nematode that connects to the esophagus.

Bud scar Ring or indentation left on the surface of a mother cell where the bud or daughter cell developed and then detached.

Buffy coat Layer of white blood cells and platelets between the plasma and the red blood cell mass when blood is centrifuged for separation.

Buffered formalin A phosphate-buffered 10% formalin solution that is used as a fixative for a variety of tissues and parasites for microscopy.

Bulb The esophageal bulb is at the posterior end of the esophagus that contains glands in nematodes.

Bulla (plural Bullae) Large blebs or blisters, filled with fluid, in or just beneath the epidermal layer of skin.

Bursitis Inflammation of a bursa, which is a small sac lined with synovial membrane and filled with fluid interposed between parts that move on each other.

Butt Lower portion of artificial culture medium in a tube while the upper portion is distributed in the form of a slanted surface, leaving an air space between the slant and the opposite wall of the tube.

Butyrous Butterlike consistency.

C

Calabar swelling A transient nonerythematous swelling that is an allergic response to a microfilarial infection.

Calcofluor white A fluorescent (white-blue) stain that binds to structures that contain cellulose and chitin. Predominantly used for visualizing fungi in tissues.

Calibrated loop Bacteriologic loop that is calibrated to deliver a specified volume of fluid. Used as a means of semi-quantitating the number of microorganisms present in a urine culture.

CAMP test A diffusible extracellular protein (CAMP factor) named after Christie, Atkins, and Munch-Peterson that is produced by specific organisms (e.g., group B streptococci) and acts synergistically with the beta-lysin of *Staphylococcus aureus* to cause enhanced lysis of red blood cells forming a flame-shaped ("campfire") pattern on blood agar.

Canaliculitis Inflammation of the lacrimal (tear-secreting gland of the eye) canaliculi (narrow channels for nerves, veins, or capillaries).

Candle jar A jar with a lid providing a gas-tight seal in which a small white candle is placed and lit after the bacterial culture plates have been placed inside. Candle will burn until the oxygen concentration has been lowered to the point at which it will no longer support the flame. Atmosphere of such a jar has a lower oxygen content than room air and a carbon dioxide content of about 3%.

Cannula An artificial tube for insertion into a tube or cavity of the body.

CAPD Chronic ambulatory peritoneal dialysis.

cAST Commercial/computerized antibiotic susceptibility testing.

Capnophilic Term used to describe microorganisms that demonstrate enhanced growth in an incubation atmosphere with increased carbon dioxide concentration.

Capsid Protein layer or coat surrounding viral nucleic acid core.

Capsomere Protein subunits of the viral capsid.

Capsule Gelatinous material surrounding a microorganism's cell wall, usually composed of polysaccharides and protein.

Carbuncle Enlarged cluster of red, swollen, and painful boils.

Carrier A host that harbors a pathogenic organism but has no disease or damage because of the presence of the pathogen.

Caseous Cheeselike; necrotic tissue, cells, and fluid accumulation.

Cat scratch disease (CSD) Disease caused by *Bartonella henselae* that is transmitted by a bite, lick of an open wound, or scratch from a domestic or wild feline (cat).

Catabolic (catabolism) Reactions that are degradative in nature; may result in the generation or formation of energy (ATP).

Catalase Bacterial enzyme that breaks down peroxides, resulting in the formation of water and oxygen.

Catarrhal stage The first stage of whooping cough (*Bordetella pertussis*) that appears similar to a cold with a runny nose lasting 1 to 2 weeks.

Cathartics Medications that accelerate the rate of passing feces or defecation without softening.

Catheter Flexible tubular (rubber or plastic) instrument used for withdrawing fluids from (or introducing fluids into) a body cavity or vessel (e.g., urinary bladder catheter).

Cation A positive ion.

cDNA See complementary DNA molecule.

Cell culture *In vitro* cultivation and maintenance of eukaryotic cells in artificial growth medium.

Cell envelope Outer structure of a cell that includes the cell membrane, cell wall, and outer cell membrane, if present.

Cell line A cell culture that has specific characteristics that are maintained and that has been passed (subcultured) *in vitro.*

Cell line, continuous Line of tissue cells that is maintained in a specific phase of growth by serial passage (subculturing) of an established cell line.

Cell line, primary Preparation of a cell culture from a specific tissue by isolating the cells using mechanical or enzymatic methods and establishing the cell culture in a flask with appropriate artificial growth medium.

Cell-mediated immunity (CMI) or cellular immunity Human specific immune response carried out by special lymphocytes of the T (thymus-derived) class.

Cell membrane (cytoplasmic membrane) Contains the internal contents of the cell (cytoplasm or cytosol) from the environment. Serves as an osmotic barrier and controls which molecules enter and leave the cell.

Cellular arrangement Characteristic cellular arrangement that is identifiable for groups of microorganisms such as clusters, chains, pairs or tetrads, etc. Cellular arrangement is determined genetically by the means of cellular division.

Cellular immunity See cell-mediated immunity.

Cellular membrane See cytoplasmic membrane.

Cellular morphology Characteristic, repeating cellular shape that is generally monomorphic (single shape) and identifiable for specific microorganisms such as bacilli, cocci, vibrios, and spirillum.

Cellulitis Inflammation of the layers of the subcutaneous tissue.

Cell wall Outer layer of a cell that is present in some cells between the cell membrane and the internal contents. Imparts rigidity and structural integrity to the cell.

Central nervous system (CNS) The CNS consists of the brain and the spinal cord.

Central vacuole (body) form Commonly identified morphological form of the intestinal protozoan *Blastocystis hominis*, where a central vacuole encompasses most of the internal cell with a small ring of cytoplasm visible on the periphery.

Cephalic Referring to the head, or anterior structure, head-end of a parasite.

Cercariae Tailed, free-swimming larval stage of a trematode.

Cerebriform Appearance that is convoluted with brainlike folds. Term is used to describe fungal macroscopic colony morphology (topology).

Cereulide A heat-stable toxin that is produced by *Bacillus cereus* that causes nausea and vomiting (emetic).

Cervical Pertaining either to the neck or to the cervix of the uterus.

Chancre A painless genital ulcer generally associated with the primary stage in syphilis.

Charcot-Leyden crystals Slender crystals shaped like a double pyramid with pointed ends, formed from the breakdown products of eosinophils and found in feces, sputum, and tissues; indicative of an immune response that may have parasitic or nonparasitic causes.

Chemical disinfectant Chemicals that deactivate or kill some of the living organisms on inanimate surfaces. One of the most common is chlorine bleach.

Chemical hygiene plan All laboratories are required to have a chemical hygiene plan to protect the employees from exposure to health hazards and injuries, as well as processes and procedures for treatment when needed.

Chemical sterilant See biocides.

Chemotaxis Directed movement either toward or away from a chemical based on a concentration gradient.

Chemotaxonomic A method of classification that compares the biochemical make-up of cells to determine identity and relatedness, such as fatty-acid and protein profiles or cell wall composition.

Chemotherapeutic Chemical agent used to treat a disease; in microbiology typically, an infection caused by a bacteria, fungus, parasite, or virus. An antimicrobial, antifungal, antiviral, or antiparasitic agent.

Chlamydoconidia See chlamydospore.

Chlamydospore Thick-walled spore formed directly from a vegetative cell or hyphae that may be terminal or intercalary (in between).

Cholangitis Infection of the common bile duct.

Cholera A disease of the small intestine that results in severe fluid loss as a result of a bacterial infection, generally caused by strains of *Vibrio cholerae.*

Cholestasis Interference with the flow of bile from the liver.

Chorioamnionitis Infection in the uterus of the amnion and chorion fetal membranes during pregnancy.

Chorioretinitis Inflammatory process in the back of the eye involving the retina and the choroids.

Chromatoidal bar Aggregations of ribosomes that may be identified in the cyst of an amoeboid protozoan.

Chromatography Method of chemical analysis by which a mixture of substances is separated by fractional extraction or adsorption or ion exchange on a porous solid.

Chromogen An organism that can produce pigment during colonial growth is pigmented (e.g., *Flavobacterium* spp., yellow).

Chromogenic Giving rise to color, as chromogenic substrates for colored products of biochemical reactions or chromogenic bacteria that produce pigmented colonies.

Chromosome Structural organization of the deoxyribonucleic acid that carries the genetic code for an organism. Chromosome numbers vary from one organism to another and are double-stranded linear or circular molecules.

Chronic Condition that persists for a long period, resulting in slow pathogenesis or damage to the patient.

Chyluria Lymphatic rupture resulting in lymph fluid excreted into the urine.

Cilia Hairlike projections on the outside of eukaryotic cells. Cilia line the mucosal cells of the bronchi and trachea to move mucus and particles trapped in the respiratory tract, referred to as the mucociliary escalator. Also, present on protozoan, eukaryotic organisms as organelles for locomotion.

Clavate Club-shaped. Term used to describe macro- or microconidia of fungal organisms.

Cleavase An enzyme that is used in molecular diagnostics that is used to cleave an unpaired overlapping end of a synthetic oligonucleotide.

Clinical resistance The level of antibiotic resistance in an organism when the drug can no longer be effectively used for treatment.

Clonal expansion A process where a single cell multiplies and divides to produce activated clones of the specific cell. Term is used to describe the multiplication of T lymphocytes and B lymphocytes in the specific adaptive immune response.

Clone Group of cells or microorganism of identical genetic makeup derived from a single common ancestor.

Clue cell A vaginal epithelial cell that is coated with bacteria associated with bacterial vaginosis.

Coagglutination Agglutination of particulate antigens that aggregate with antigens with more than one specificity. An example is protein A–containing cells of *Staphylococcus aureus* coated with antibody molecules when exposed to corresponding antigen.

Coccidia Group of spore-forming protozoans.

Codon A set of three nucleotides.

Coenocytic hyphae See aseptate. May also be sparsely septated.

Coenurus Larval form of a tapeworm or cestode.

Coenurosis Infection caused by a larval form of a tapeworm or cestode.

Cold enrichment The incubation of a microbial culture in a temperature below body temperature (35°C to 37°C) to enhance the growth of a microorganism and eliminate the growth of contaminating organisms incapable of growth at the lower temperature.

Cold sterilization Use of chemicals (glutaraldehyde, OPA, or peracetic acid) to remove all life forms from inanimate surfaces without the use of heat.

Colitis Inflammation of the mucosa of colon.

Columella Structure on the top stipe of a reproductive fungal element that comes into direct contact with the sporangiospores inside the sporangia.

Colonial morphology Visible characteristics of microorganisms grown on artificial media. Some examples include shape, elevation, margins, texture, pigment, and more.

Colonization Growth of a microorganism in or on a human host without causing damage.

Colonizer See nonpathogenic.

Colony Macroscopically visible growth of a microorganism on solid artificial culture medium.

Colony-forming unit (CFU) Colony count.

Combination media Microbiological media that has two properties for the growth of microorganisms, such as selective and differential.

Commensal Microorganism living on or in a host but causing the host no harm.

Community-acquired Pertaining to outside the hospital, such as a community-acquired infection.

Competent Term used to describe cells or a microorganism that can take up nucleic acids from the external environment naturally or following chemical treatment.

Complement (system or proteins) Set of serum proteins that are included in a catalytic cascade during immune activation. Proteins are cleaved into different fragments; each fragment has a specific function that differs from the original intact protein.

Complement fixation test (CF) Antigen-antibody test based on fixation of complement in the presence of both elements and use of an indicator system to identify complement fixation.

Complementary Term used to describe the ability of two molecules to bind together by pairing chemical and physical structure, such as complementary nucleic acid sequences.

Complementary DNA molecule (cDNA) A DNA sequence that has been synthesized from an RNA molecule. In eukaryotic DNA technology, the cDNA is complementary to the RNA and does not include the introns that are found in the original DNA template used to transcribe the RNA. Remember, following transcription, eukaryotic RNA is processed and spliced, and introns are removed.

Complex Commonly used to describe two or more species of organism that cannot be distinguished based on phenotypic, metabolic, or clinical presentation. Individual species may be referred to as molecular siblings.

Composite transposon A composite transposon includes an internal gene or coding sequence for an antibiotic resistant or other virulence determinant, flanked on both sides by an insertion sequence.

Condylomata A lesion on the skin that is elevated and irregular; resembles a wart.

Congenital A disease or infection that existed before birth.

Conidia Asexual spores in fungi.

Conjugation The transfer of genetic material between bacteria by direct contact via tubular structures referred to as pili.

Conjunctivitis Inflammation of the conjunctivae or membranes of the eye.

Constant region Portion of the antibody that is identical within a specific isotype (e.g., IgG), and represents the C or carboxyl terminus of the glycoprotein that binds to immune cells.

Constitutive An essential metabolic component or chemical such as an enzyme that is produced continuously independent of changing environment or nutritional conditions.

Continuous cell line A group of cells that can be grown repeatedly in artificial culture while maintaining the original characteristics of the cell line.

Contrast The ability to differentiate one item from another. Stains are used to add contrast to microorganisms to improve the ability to differentiate and increase the contrast of the organism in comparison to the background during microscopy.

Convalescent sera Serum collected later in the course of an illness than the acute serum, usually at least 2 weeks after initial collection.

Convalescent stage The period following an illness when an individual begins to improve or recover.

Copulatory bursa A structure identifiable on some species of male helminths that is used to attach or hold the female worm by the male during sexual mating.

Coracidium A ciliated larva of a helminth found in water that infects an intermediate host in the parasite life cycle.

Coremia Clusters of conidiophores tied together; resembles a bundle of threads.

Corepressor A molecule that combines with another repressor molecule, activating the repressor and preventing transcription of a specific genetic sequence.

Corrosive A type of chemical that erodes another substance or material.

Coryneform Club- or rod-shaped gram-positive bacterium.

Counter stain See secondary stain.

CPE See cytopathogenic (cytopathic) effect.

Creutzfeldt-Jakob disease Debilitating prion-caused disease characterized by dementia, ataxia, delirium, stupor, coma, and death; has been transmitted by organ transplant.

Critical concentration The concentration of a drug is the amount of drug required to prevent growth above the 1% threshold of the test population of tubercle bacilli.

Critical value (panic value) A laboratory result that indicates a serious state or result for a patient, prompting immediate notification of the primary care provider.

Crossing point See threshold cycle.

Cross-reaction When an antibody for a specific antigen reacts with a similar antigen that is different from the immunogen the antibody is directed to.

Croup See laryngotracheobronchitis. Inflammation of upper airways (larynx, trachea) with respiratory obstruction, often caused by virus infections in children.

Crush prep See squash prep.

CSF Cerebrospinal fluid.

Culdocentesis Aspiration of fluid from the cul-de-sac by puncture of the vaginal vault.

Cut-off value See threshold.

Cutting plates Two large ventral platelike structures in the buccal capsule of a hookworm, *Necator* spp., used to aid in feeding.

Cycling probe technology This technique uses an RNA probe between a reporter and a quencher molecule. The center RNA portion of the molecule is degraded by RNase H releasing the quencher from the reporter resulting in fluorescence. This continues in subsequent cycling with another probe binding and continuing through the reaction.

Cyst A cyst may be a pocket of fluid within a tissue. A parasitic cyst is a reproductive stage of the organism that may be embryonated or unembryonated and is often resistant to the environment and may be the infective stage of the parasite.

Cysticercoids Larval stage of a tapeworm.

Cysticercosis Tissue infection caused by the larval stage (cysticercoid) of a tapeworm.

Cystitis Inflammation of urinary bladder, most often caused by bacterial infection.

Cytoadherence Some organisms can adhere or stick to other cells in biological organisms. Some species of malaria, for instance, will stick to the epithelial cells of the peripheral vessels in the human body.

Cytocentrifugation Specialized centrifuge where the hydraulic forces of the liquid cause the fluid to move away from the sediment that is collected on an absorbent material, leaving the particulate matter and cellular debris in the center of the microscope slide.

Cytokine Group of biochemicals that are released by specific cells during inflammation that influence other cells.

Cytopathic effect (CPE) Visible effect or physical changes associated with a specific virus infection seen in cell culture.

Cytoplasm Fluidlike portion of the cell that contains molecules or various particles and is enclosed within the cell membrane.

Cytoplasmic (cellular) membrane Membrane that encloses the cytoplasm of the cell.

Cytosol The fluid portion of the cytoplasm.

Cytostome Opening in microorganisms that is an invagination or structure that functions in the uptake of nutrients; a primitive mouth.

Cytotoxic T cells (Tc) Specific subset of T lymphocytes that targets and kills tumor cells or other human cells that are abnormal or infected with intracellular pathogens.

Cytotoxin Toxin that produces cytopathic effects *in vivo* or in a tissue culture system.

D

Dacryoadenitis Inflammation of the lacrimal (tear) glands.

Dacryocystitis Inflammation of the lacrimal sac, due to a blockage in the tear duct.

Dark-field microscopy Technique used to visualize very small microorganisms or their characteristics by a system that permits light to be reflected or refracted from the surface of objects being viewed. The background field appears dark and the microorganisms appear bright.

Deamination The removal of an amine group from an amino acid resulting in a decrease in the pH of the medium.

Debridement Surgical or other removal of dead or dying tissue. Typically used to remove the infecting organism and stop the spread of infection.

Decarboxylation The removal of a carboxyl group from an amino acid, often resulting in the formation of CO_2. This reaction will only occur in an anaerobic environment in an acidic pH.

Decolorizer Solution used during staining processes to remove excess stain. Different chemicals are used in different staining procedures.

Decontamination Process of rendering an object or area safe for unprotected people by removing or making harmless biologic or chemical agents.

Decorticated Removal of outer covering. Lacking the mammillated outer covering of a helminth egg.

Decubitus ulcer A craterlike defect in skin and subcutaneous tissue caused by prolonged pressure on the area. This occurs primarily over bony prominences of the lower back and hips in individuals who are unable to care for themselves well and unable to roll or move periodically; also known as a pressure sore or bedsore.

Defensins Molecules naturally produced by animals to defend against bacterial infections and disease.

Definitive host Host in which the sexual reproduction of a parasite occurs; required in the parasite's life cycle.

Dematiaceous See melanized.

Denaturation Process by which the structure of a molecule is disrupted using heat and chemicals to break the bonds. The term is generally used to describe double-stranded DNA becoming single-stranded by heating or chemical means; also referred to as melting and separating the secondary through quaternary structures of protein folding using heat and chemical buffers.

Dendritic cells White blood cells that are distributed throughout the tissues of the body that are primary phagocytes, which digest and present antigens to specific immune cells.

Denticle Small extension where a conidium is attached.

Deoxynucleotide triphosphates (dNTPs) Basic structure of nucleic acids, a nucleotide that binds to deoxyribose to form the building blocks of deoxyribonucleic acid. The "N" stands for any of the nitrogenous bases.

Deoxyribonucleic acid (DNA) The molecule that contains the genetic code for most living things. Consists of a sugar-phosphate backbone, nitrogenous bases, and deoxyribose.

Dermatome Area of the skin attached to a single nerve.

Dermatophyte A cutaneous fungus that infects the hair, skin, or nails.

Dermis Layer of skin beneath the epidermis that is composed of dense connective tissue rich in blood and nerve supply.

Desquamation Shedding or scaling of skin or mucous membrane.

DFA test Direct fluorescent antibody test.

DIC See disseminated intravascular coagulation.

Dichotomous Branching in two directions.

Differential media Employ some factor (or factors) that allow colonies of one bacterial species or type to exhibit certain metabolic or culture characteristics that can be used to distinguish them from other bacteria growing on the same agar plate. Differential factors are generally visible differences based on metabolic capabilities that can be detected using dyes or indicators that change color with a change in pH or other chemical reaction.

Differential stain A stain that includes two dyes, one primary and one secondary that are sequentially used to stain a structure. Based on the process and affinity of the dyes, the stains attach to different components in a cell, providing a means to differentiate and identify specific organisms based on unique chemical properties or structures.

Digital microscopy An automated or semiautomated system that uses sophisticated software and unique technology that permits laboratories to acquire microscopic digital images of using a web-based interface. This interface allows images using a fully automated microscope to be viewed on a single screen.

Diluent Fluid used to dilute a substance or solute.

Dimorphic fungi Fungi with both a mold phase and a yeast phase.

Diploid cell line A cell line that contains two complete sets of genes or chromosomes that can be passed or subcultured for an extended period in cell culture.

Direct life cycle A parasitic life cycle where the organism remains in a single host type for the entire life cycle and can be transmitted directly between hosts.

Direct microscopic examination A microscopic examination directly from the specimen or sample, prior to any enhancement or growth techniques to isolate organisms from the specimen.

Direct smear A smear or spreading of a sample or specimen from the collection container, without further testing or alteration in the specimen or sample.

Direct transmission The acquisition of an infectious agent or microorganism by coming into direct contact with the microbial reservoir of the agent or organism.

Direct wet mount A preparation from clinical material suspended in sterile saline or other liquid medium on a glass slide and covered with a coverslip; used for microscopic examination to detect microorganisms in clinical material and to detect motility directly.

Disease An abnormal physiological state or condition where the patient demonstrates some type of damage or dysfunction.

Disinfectant Agent that destroys or inhibits microorganisms that cause disease on inanimate objects.

Disinfection The process of removing most of the microorganisms from the surface of an inanimate object or surface.

Disjuncture cell A cell that fragments or lyses to release a spore. After release of the spore, the cell appears as an empty cell.

Disk diffusion (antimicrobial susceptibility testing) A technique that uses small filter-paper disks impregnated with antibiotics. The disks are placed on artificial media that has been inoculated with a lawn of organism. The antimicrobial diffuses into the media and is tested for ability to inhibit the growth of the organism.

Disseminated intravascular coagulation Numerous small blood vessels become clogged with blood clots and bleeding occurs because of the depletion of coagulation factors.

Diurnal Normal day activity, where an organism has a regular day/night life cycle.

DNA See deoxyribonucleic acid.

DNA minor groove A location on double-stranded DNA in which the strand backbones are closer together on one side of the helix than on the other.

dNTPS See deoxynucleotides.

Donovan body Intracellular amastigotes inside tissue cells of the reticuloendothelial system.

Donovanosis A condition caused by *Klebsiella granulomatis* that causes a sexually transmitted disease also known as granuloma inguinale.

Droplet nucleus An aerosolized particle that contains a potentially infectious agent that generally travels three feet or less.

Duplex See hybrid.

Dx Diagnosis.

Dysentery Inflammation of the intestinal tract, particularly the colon, with frequent bloody stools (e.g., bacillary dysentery).

Dysesthesias Pain when touched.

Dysgonic Growing poorly (bacterial cultures).

Dysnomia Demonstrating difficulty recalling verbal or written material upon request.

Dyspareunia Persistent genital pain during sexual intercourse.

Dysuria Painful or difficult urination.

E

Ecchymosis Discoloration of the skin or bruising due to bleeding under the skin.

Echinulate Spines or spikey, rough looking.

Ectocyst Part of a hydatid cyst, the outermost layer.

Ectoparasite Organism that lives on or within the superficial layers of the skin without gaining access to internal organs.

Ectothrix Outside of hair shafts.

ECV See epidemiologic cutoff value.

Edema Excessive accumulation of fluid in tissue spaces.

Effacement Shortening, thinning, or destruction of epithelial cells.

Effusion Fluid escaping into a body space or tissue (e.g., pleural effusion).

Egg packet Diagnostic form of the tapeworm *Dipylidium caninum* found in the feces of infected individuals.

Electron microscopy Microscope that utilizes a beam of electrons to achieve magnifications more than 100,000 times.

Elementary body The infectious stage of *Chlamydia* or a cellular inclusion body of a viral disease.

ELISA Enzyme-linked immunosorbent assay.

Elution Process of extraction by means of a solvent.

EMB Eosin-methylene blue (agar plate).

Emetic toxin Preformed bacterial toxin that induces vomiting.

Empiric therapy Used to initiate therapy based on the physician determining the most likely organism causing a patient's clinical symptoms and then selecting an antimicrobial that, in the past, has worked against that organism in a hospital or geographic area.

Empyema Accumulation of pus in a body cavity, particularly empyema of the thorax or chest.

Encephalitis Inflammation of the brain.

Endocarditis A serious infection of the endothelium of the heart, usually involving leaflets of the heart valves where destruction or distortion of valves occurs because of the formation of vegetation that may lead to serious physiologic disturbances and death; also, an inflammation of the endocardial surface (much less common).

Endocervix Mucous membrane of the cervical canal.

Endocyst The layer within a hydatid cyst that is deepest within the structure.

Endocytosis Method by which a cell membrane extends and surrounds a particle or cell, then invaginates and engulfs the material in an internal vesicle or phagosome.

Endoflagella Axial filament or internal flagella found within a prokaryotic organism, spirillum, or spirochete.

Endogenous Developing from within; internal cause.

Endoparasite Parasite that lives inside the human body; penetration and reproduction within human organ systems causing damage.

Endophthalmitis Inflammation of internal tissues of the eye; may rapidly destroy the eye.

Endospore A spore that develops inside a bacterial cell during poor environmental conditions such as desiccation or lack of available nutrients; nonvegetative.

Endothelium Squamous epithelium lining of the blood vessels.

Endothrix Within the hair shaft.

Endotoxin Substance containing lipopolysaccharide complexes found in the cell wall of bacteria, principally gram-negative bacteria; believed to play an important role in many of the complications of sepsis such as shock, disseminated intravascular coagulation, and thrombocytopenia.

Enrichment media Used in cultures for the enhancement of growth of an organism. The media may be selective or contain specific nutrients or chemicals to increase the growth of an organism or group of organisms.

Enteric fever Typhoid fever; paratyphoid fever.

Enteroinvasive Capable of invading the mucosal surface and sometimes the deeper tissues of the bowel.

Enterotoxin Toxin affecting the cells of the intestinal mucosa.

Entropion Folding inward of the eyelid.

Enzyme-based test Biochemical test that measures the activity of an enzyme to identify a specific metabolic pathway that can be used to correlate with other laboratory results in an identification scheme. Phenotypic, generally based on a visible or measurable chemical reaction.

Enzyme-linked immunosorbent assay (ELISA) An immunologic assay that uses an enzyme conjugated to antibodies to produce a visible endpoint.

Epidemiologic cutoff value Distribution of the minimum inhibitory concentration that is used to separate bacterial populations into those with acquired resistance and the original population.

Epidemiology The study of the occurrence and distribution of disease and factors that control presence or absence of disease.

Epidermis Outermost layer of skin made of layered squamous epithelial cells.

Epididymitis Inflammation of the epididymis characterized by fever and pain on one side of the scrotum; seen as a complication of prostatitis and cystitis.

Epifluorescence The principle of fluorescent microscopy in which the excitation light is emitted from above.

Epigenetic Influences on the expression of genes that are not controlled by genetic mechanisms.

Epiglottitis Inflammation of the epiglottis, a structure that prevents aspirating swallowed food and fluids into the tracheobronchial tree; a serious infection because the swollen epiglottis may block the airway.

Epimastigote Life cycle form of a *Trypanosoma* spp. that is found in the salivary glands of the vector.

Episome Small genetic element that exists as an extrachromosomal circular molecule that replicates independently of the chromosome or while integrated in the chromosome.

Epithelium Tissue composed of contiguous cells that forms the epidermis and lines hollow organs and all passages of the respiratory, digestive, and genitourinary systems.

Epitope The molecule or chemical groups on an antigen recognized by the specific antibody.

Epizootic A disease that is temporarily present in a given population of animals.

Erysipelas An acute cellulitis caused by group A streptococci or *Erysipelothrix* spp.

Erysipeloid Bacterial infection caused by *Erysipelothrix* spp., generally an acute dermatitis resembling erysipelas.

Erythema Redness of the skin from various causes.

Erythema migrans A bullseye-shaped rash associated with Lyme disease.

Erythema nodosum Skin inflammation in the fatty layers that appear as tender, red, painful lumps.

Erythrasma A minor, superficial skin infection caused by *Corynebacterium minutissimum*.

Eschar A black, necrotic lesion associated with cutaneous anthrax.

Etiology (etiologic) Cause or causative agent.

Eugonic Growing luxuriantly (bacterial cultures) on artificial media.

Eukaryotic Organisms with a true nucleus, in contrast to bacteria and viruses.

Exanthem Skin eruption as a symptom of an acute disease, usually viral.

Exanthem subitum Viral illness that appears with a high fever, sore throat, and a faint red rash.

Exfoliative toxin Toxin that causes a blistering and peeling of the skin.

Exoantigen test *In vitro* immunodiffusion test method for identifying fungal hyphae as *Histoplasma, Blastomyces*, or *Coccidioides*.

Exoerythrocytic cycle Portion of the malarial life cycle occurring in the vertebrate host in which sporozoites, introduced by infected mosquitoes, penetrate the parenchymal liver cells and undergo schizogony, producing merozoites, which then initiate the erythrocytic cycle.

Exogenous From outside the body.

Exotoxin A toxin produced by a microorganism that is released into the surrounding environment.

Extension PCR cycle, where the polymerase synthesizes or extends the new strand from the 3′ hydroxyl of the primer. Generally carried out at 72°C.

Exudate Fluid that has passed out of blood vessels into adjacent tissues or spaces; high protein content.

F

Fab region The region or fragment of the antibody that binds the epitope of an antigen.

Facialis Of the face.

Facultative anaerobe Microorganisms that are capable of growth under either anaerobic or aerobic conditions.

Fascia Membranous covering of muscle.

Fastidious An organism that requires a special nutritional or environmental condition for growth.

Favus Superficial disease of the scalp caused by a dermatophyte.

Fc region The Fc region of the antibody is the tail end or bottom of the Y-shaped molecule that binds to cells.

Febrile Demonstrating a fever.

Feeding (viral cultures) During the cultivation of viral cultures, periodic replacement of the nutritional fluid in the culture is termed feeding.

Fermentation Anaerobic decomposition of carbohydrate that results in the production of acid, alcohol, and/or gas.

Fibrinolysin The breakdown of fibrin clots due to enzymatic action.

Filamentous Threadlike.

Filariform The infective larval stage of roundworms for a human host.

Filtration Method to remove contamination such as microorganisms from heat-labile liquids by pulling the solution through a cellulose acetate or cellulose nitrate membrane with a vacuum.

Fimbriae Proteinaceous fingerlike surface structures of bacteria that provide for adherence to host surfaces. Also capable of antigenic variation in some microorganisms.

Fistula Abnormal opening between two surfaces or between a viscus or other hollow structure and the exterior.

Flagella Complex structures mostly composed of the protein flagellin that are responsible for bacterial motility.

Flammable A material or chemical that can easily be set on fire.

Flatulence The production of gas, often following the ingestion of food.

Floccose Cottony, in tufts.

Flocculation test A soluble antigen and antibody that generate an end-product that forms macroscopically or microscopically visible clumps.

Fluorescence microscopy A microscope that uses various wavelengths of ultraviolet light and filters to excite and visualize fluorophores attached to antibodies or other molecules for the visualization of microorganisms directly or in tissues.

Fluorescent Emission of light by a substance (or a microscopic preparation) while acted on by radiant energy, such as ultraviolet rays, as in the immunofluorescent procedure.

Fluorochrome A dye that becomes fluorescent or self-luminous after exposure to ultraviolet light.

Fluorophore A fluorescent molecule that can absorb light energy and then is elevated to an excited state that is released as fluorescence in the absence of a quencher.

Folliculitis Inflammation or infection of a hair follicle.

Fomite (vehicle) Any inanimate object that may be contaminated with disease-causing microorganisms and thus serves to transmit disease.

FTA Fluorescent treponemal antibody.

FTA-ABS Fluorescent treponemal antigen-antibody absorption: test; indirect fluorescent antibody stain used to detect antibodies directed against whole-cell antigens of *Treponema pallidum* (syphilis bacillus).

Fungemia Presence of viable fungi in blood.

Fungus (plural Fungi) Saprophytic eukaryotic organism that obtains nutrients from dead or dying organic matter.

FUO Fever of unknown origin.

Furuncle A fluid-filled or pus-filled enlargement at the base of an inflamed or infected hair follicle.

Fusiform Spindle-shaped, as in the anaerobe *Fusobacterium nucleatum*.

Fusion protein (F protein) A protein on the envelope of a virus that functions to assist in fusion of the viral envelope with the host cell membrane during entry to the host cell.

Fusoid A structure that has a wide center and tapered at both ends; scientific term for spindle-shaped.

G

Gametocyte A cell that divides through the process of meiosis, forming a haploid gamete.

Gametogony The process or term used to describe the formation of gametes.

Gamma hemolysis No hemolysis of red blood cells on artificial media.

Gamogony Fission (dividing in half) resulting in the production of sporozoan gametes.

Gangrene Death of tissue resulting from disease, injury, or failure of blood supply.

Gas-liquid chromatography (GLC) A method for separating substances by allowing their volatile phase to flow through a heated column with a carrier gas and measuring the time required to detect their presence at the distal end of the column.

Gastric aspirate Fluid aspirated from the stomach via a tube placed in the stomach by way of the nose or mouth.

Gastroenteritis Inflammation of the mucosa of the stomach and intestines.

GC Gonococcus.

Gene A sequence of nucleic acids that code for a functional product.

Gene expression The visible effect of a gene or phenotypic evidence.

Generalized transduction The movement of any genetic material from a host cell to another via a bacteriophage or virus.

Generation time The amount of time it takes a microorganism to divide into daughter cells.

Genetic code Nucleotide triplets on either DNA or RNA that correlate to a specific amino acid.

Genetic shift Major change in the nucleic acid of a virus. Often associated with influenza viruses that exchange RNA genome segments with another viral strain.

Geniculate Bent.

Genital primordium Genital swelling and opening apparent on a parasite.

Genogroups Viruses in a specific genus that are related.

Genome The entire genetic make-up in an organism.

Genome-to-genome distance A nucleotide sequence technique that uses calculations to determine the relatedness of organisms at the genetic level. The technique is representative of the previous manual DNA-to-DNA hybridization technology.

Genomospecies A species that can be differentiated using genetic or molecular sequences, not considered an actual recognized independent species.

Genomovars A variety of an organism that is genetically different but phenotypically indistinguishable.

Genotype Related to characteristics of an organism's genetic makeup; constituent nucleic acids.

Genotypic A characteristic that is determined by the genetic makeup or nucleic acid sequence and epigenetic mechanisms.

Germicide An agent that destroys germs; disinfectant.

Germ tube Tubelike process, produced by a germinating spore that develops into a regular, hyphal-like structure.

Giant cell See syncytia.

Glabrous Smooth fungal colonial morphology without aerial hyphae.

GLC Gas-liquid chromatography.

Goblet cell Cells found in the respiratory, gastrointestinal, or reproductive tracts. The cells are shaped like goblets with the cellular organelles located on one end with the opposite end containing numerous mucin-filled secretory vesicles.

Granulocytopenia Reduced number of granulocytic white blood cells in the blood.

Granuloma Aggregation and proliferation of macrophages to form small (usually microscopic) nodules; may be associated with a variety of infections, including tuberculosis, forming a hard granuloma or tubercle.

Granuloma inguinale Sexually transmitted disease caused by *Klebsiella granulomatis* that demonstrates a painless, inflammatory reaction in or near the genitals.

Granulomatous amebic encephalitis (GAE) A disease caused by free-living amebae that demonstrates as an acute or chronic infection that is often fatal.

Grocott methenamine silver stain (GMS) A histological silver stain, used to identify fungal structures in tissue.

Growth-based tests Microbiological tests that require an incubation period at a specified temperature and increased growth of the microorganism *in vitro.* Failure for the organism to grow results in an invalid test (end-product measurement) or negative test (nutritional or selective growth).

Growth medium Chemical formula of nutrients and vitamins required for the cultivation of microorganisms. May be liquid, solid, or semisolid media.

Guanidinium isothiocyanate Chemical compound that denatures proteins. Used in nucleic acid extractions to denature enzymes such as RNAse or DNAse that would damage or reduce the yield of the extraction.

Gumma A soft, painless, noninfectious granuloma-like lesion.

H

HAART See highly active antiretroviral therapy.

HACEK *Haemophilus, Aggregatibacter, Cardiobacterium, Eikenella,* and *Kingella.* The *Haemophilus* organisms in this group have been reclassified as *Aggregatibacter,* but the acronym remains unchanged in the clinical environment.

Halogens (chemical disinfectant) Nonmetal element with low melting and boiling points; may exist as gases, liquids, or solids. The chemicals generally kill microorganisms when used in disinfectants.

Halophilic Preferring high halide (salt) content; salt loving.

Hansen disease Leprosy, a disease caused by *Mycobacterium leprae*.

Haverhill fever A disease caused by the microorganism *Streptobacillus moniliformis*, also known as rat-bite fever.

Hemadsorption Ability of certain virally infected cells to bind erythrocytes; mediated by glycopeptide adherence molecules (induced by viral activities within the cell) on the cell's surface.

Hemagglutinin (HA) A glycoprotein found on the surface of a virus particle that participates in the attachment and entry of the virus into the host cell. Exists in multiple antigenic forms or serotypes.

Hemagglutination Agglutination of red blood cells caused by certain antibodies, virus particles, or high molecular weight polysaccharides.

Hematogenous Disseminated by the bloodstream.

Hematuria Blood in the urine.

Hemin (X-factor) Iron containing compound found inside red blood cells that is a required nutritional factor for some fastidious microorganisms.

Hemiparesis Paralysis on one side of the body.

Hemolysin A substance that lyses red blood cells.

Hemolysis, alpha Partial destruction of, or enzymatic damage to, red blood cells in a blood agar plate, leading to greenish discoloration about the colony of the organism producing the alpha hemolysin.

Hemolysis, beta Total lysis of red blood cells about a colony on a blood agar plate, leading to a completely clear zone surrounding the colony.

Hemolysis, gamma No hemolysis is seen with organisms classified as gamma-hemolytic.

Hemolytic uremic syndrome (HUS) Inflammation and damage to the small capillaries in the kidneys that leads to renal insufficiency and may result in death.

Hemoptysis Coughing up blood.

HEPA High-efficiency particulate air filter; used in biological safety cabinets to trap pathogenic microorganisms.

Herd immunity Immunity to an infectious agent in a high percentage of a given population of people that helps prevents spread of the disease.

Hermaphroditic An organism that can produce gametes of both male and female sexes.

Herpes Inflammation of the skin characterized by clusters of small vesicles (e.g., caused by herpes simplex); disease caused by herpes simplex virus.

Heterophile antibody Nonspecific, weak antibodies that are produced in a variety of infectious diseases and other medical conditions.

Heterotroph Organism that requires an external organic carbon source for energy production.

Hexacanth embryo A six-hooked embryo of a tapeworm.

Highly active antiretroviral therapy (HAART) Combination antiretroviral therapy of multiple drugs, generally three or more.

High-pressure liquid chromatography (HPLC) Similar to gas-liquid chromatography but capable of higher resolution because of increased pressure of liquid carrier that runs through the column.

Homogenization Mixing components so that the resulting mixture appears as a single component, or uniform.

Homologous recombination The act of a genetic sequence or fragment combining with another molecule by pairing with a similar sequence.

Horizontal gene transfer Genetic transfer from one organism to another, not through reproduction of the organism.

Hospital information system (HIS) Computer and software system used in a health care or hospital organization.

Howell-Jolly bodies Basophilic staining clusters of DNA found in red blood cells in the peripheral circulation.

HPLC High-pressure (or performance) liquid chromatography.

Household bleach See hypochlorite solution.

Human granulocytic anaplasmosis (HGA) Disease that is transmitted by a tick and caused by the bacterium *Anaplasma phagocytophilum.*

Human microbiome See microbiome.

Human monocytic ehrlichiosis (HME) Disease where the organism *Ehrlichia chaffeensis* infects human monocytes or macrophages.

Humoral immunity Antibody-mediated immunity.

HUS See hemolytic uremic syndrome.

Hutchinson triad Set of three clinical symptoms of deafness, blindness, and notched peg-shaped teeth associated with a diagnosis of congenital syphilis.

Hyaline Colorless, transparent.

Hyalohyphomycosis Fungal disease caused by hyaline or colorless fungal organisms.

Hybrid (duplex) Two nucleic acid strands that have complementary base sequences that have specifically bonded with each other and formed a double-stranded molecule.

Hybrid capture The use of a synthetic oligonucleotide or nucleic acid sequence to capture a complementary sequence in solution for amplification or quantitation in a molecular assay.

Hybridization Mixing of two molecular components, such as two nucleic acids or a protein and a nucleic acid under conditions where they interact and attach to each other indicating a reaction of identity, similarity, or complementation.

Hybridoma The product of fusion of an antibody-producing cell and an immortal malignant antibody-producing cell.

Hydatid cyst A large pouch generally filled with fluid and associated with an *Echinococcus* spp.

Hydatid sand Immature scolices of the tapeworm *Echinococcus* spp.

Hydrocele Fluid-filled sac within the scrotum.

Hydrogen peroxide (chemical disinfectant) A compound that is composed of hydrogen and water that is an effective disinfectant against a wide variety of microorganisms.

Hydrolysis Breakdown of a substrate by an enzyme that adds the components of water to key bonds within the substrate molecule.

Hyperalimentation Process by which nutrition (literally "extra nutrition") is provided; typically administered intravenously in subjects who are not able to absorb foods well from the gut because of disease of the bowel, in subjects in whom it is desirable to put the bowel "at rest" to promote healing, and in malnourished individuals to improve their nutritional status (e.g., before surgery); usually done over an extended period and requires the use of a special-access intravenous catheter such as a Hickman catheter.

Hyperemia Increased blood in a part, resulting in distention of blood vessels.

Hyperinfection Repeated reinfection by a parasitic worm that is already in the host.

Hypertonic Hyperosmotic fluid in comparison to another fluid that is separated by location or a membrane.

Hypertrophy Increased size of an organ resulting from enlargement of individual cells.

Hypha (plural Hyphae) Tubular cell making up the vegetative portion of mycelium of fungi.

Hypnozoites Dormant forms of malarial parasites that are found in the liver.

Hypochlorite solution (NaOCl) 5.25% to 6.15% disinfectant also referred to as household bleach.

Hypofunction Insufficient or decreased function.

Hypoperfusion Reduced blood flow.

Hypoxia Decreased oxygen content of tissues.

I

Iatrogenic Contraction of a disease or illness caused by a medical examination, procedure, or treatment.

Icteric Yellow coloration or pigmentation; jaundice.

Identification scheme Series of procedures or methods used to identify a microorganism. The extent of the identification scheme or work-up depends on the type of organism and its propensity to be the cause of a patient's infection or disease.

Idiotype The antigenic specificity of either a group of antibodies or T-cell receptor (TCR) produced from a population of cloned cells.

IFA Indirect fluorescent antibody; test that detects antibody by allowing an antibody to react with its substrate and adding a second fluorescein dye–labeled antibody that will bind to the first.

Ig, IgG, IgM, etc. Immunoglobulin, immunoglobulin G, immunoglobulin M, etc.

Immortalization See transformation.

Immunization See vaccination.

Immunodiffusion Detection of antigen or antibody by observing the precipitin line formed in a semisolid gel matrix when homologous antigens and antibodies are allowed to diffuse toward each other and react.

Immunofluorescence Microscopic method that uses a fluorescent dye linked (conjugated) to specific antibodies to determine the presence or location of an antigen (or antibody) by demonstrating fluorescence when the preparation is exposed to ultraviolet radiation.

Immunoglobulin (antibody) Synonymous with antibody; five distinct classes have been isolated: IgG, IgM, IgA, IgE, and IgD.

Immunoperoxidase stain Combination of an enzyme that catalyzes production of a colored product with an antibody to facilitate detection of certain antigens, particularly viral antigens.

Immunosuppression Depression of the immune response caused by disease, irradiation, or administration of antimetabolites, antilymphocyte serum, or corticosteroids.

Impetigo Acute inflammatory skin disease, caused by streptococci or staphylococci, characterized by vesicles and bullae that rupture and form yellow crusts.

Incineration Method of treating infectious waste. Hazardous material is burned to ashes at temperatures of 870°C to 980°C.

Inclusion bodies Microscopic bodies, usually within body cells; thought to be virus particles in morphogenesis.

Inclusion conjunctivitis Inflammation of the conjunctiva of the eye; may be caused by *Chlamydia* sp.

Indigenous flora See microbiota.

Indirect concentration wet mount The second part of the classic ova and parasite examination is a concentration step. Because many laboratories no longer do direct wet preps prior to concentration, this terminology has been used to distinguish a wet prep following concentration of the specimen.

Indirect life cycle A parasite that requires multiple hosts to complete the reproductive cycle.

Indirect microscopic examination A microscopic examination of an organism after cultivation on artificial media, not directly from the clinical specimen.

Indirect smear A smear of an organism placed on a microscope slide after cultivation of the organism on artificial media, not directly from the clinical specimen.

Indirect transmission The acquisition of an infectious agent or microorganism by coming into contact through an intervening living vector or nonliving fomite or vehicle of transmission that is not the reservoir.

Indirect wet prep A preparation of a clinical specimen that has been preserved to prevent infection or contamination killing the organisms. Associated with a concentration of a stool specimen in preservative for the identification of parasites.

Inducible A metabolic component or chemical such as an enzyme that is turned on or expressed only when required in changing environmental or nutrient conditions.

Induction The process of turning on the production of a metabolic component or chemical at the level of transcription or translation in response to changing environmental or nutrient conditions.

Induration Abnormal hardness of a tissue or part resulting from hyperemia or inflammation, as in a reactive tuberculin skin test.

Infection Invasion by and multiplication of microorganisms in body tissue resulting in disease.

Inflammation Generalized nonspecific immune response that is activated when cells within the body release chemical mediators resulting in vasodilation and increased circulation. The symptoms of inflammation include heat, redness, swelling, and pain.

Inhibitory quotient Ratio of the average peak achievable level of antibiotic in a body fluid from which an organism was isolated to the minimum inhibitory concentration of that organism.

Insertion sequence (simple transposon) Transposable element containing genes that encode the information required to move among plasmids and chromosomes.

***In situ* hybridization** Detection of nucleic acid of a pathogenic organism in tissue sections by separating the DNA into single-stranded molecules and allowing a labeled strand of homologous DNA to bind to the target. The target can be visualized by developing the label (i.e., enzymatic precipitate, fluorescence, or radiolabel).

Inspissation Process of making a liquid or semisolid medium thick by evaporation or absorption of fluid.

Integron A group of genes that move together as a cassette and includes the gene to produce the enzyme integrase that mediates the recombination event.

Integument Outer protective layer of a parasitic worm.

Intercalary Located in between two structures.

Interfacing Communicating between.

Intermediate host Required host in the life cycle in which essential larval development must occur before a parasite is infective to its definitive host or to additional intermediate hosts.

Intermittent carrier An individual colonized with a different strain of a potential pathogenic microorganism over time.

Intertriginous Location where two areas of skin rub or touch each other; folds of skin.

Intoxication Food poisoning caused by the ingestion of preformed toxins.

Intramuscular (intraperitoneal, intravenous) Within the muscle (peritoneum, vein), as in intramuscular injection.

Intracystic Inside the bladder or a cyst.

Intrinsic resistance Natural resistance to antimicrobials based on physiology; generally encoded in chromosomal sequence.

Invariant natural killer cells (iNKT cells) Special population of T cells that recognize lipid-based antigens.

Invasion When a microorganism can break through the primary and secondary immune defenses of the host.

In vitro Literally, within glass (i.e., in a test tube, culture plate, or other nonliving material). Refers to testing of a microorganism in a laboratory environment.

In vivo Within the living animal or human host.

Involution forms Abnormally shaped bacterial cells occurring in an aging culture population.

Iodine tincture Iodine in alcohol.

Ion-exchange chromatography Separation of components of a solution by chromatography based on the reversible exchange of ions in the solution with ions present in or on an external matrix.

Iso cytidine (iso C) Pyrimidine base that is an isomer of cytosine.

Iso guanosine (iso G) Purine base that is an isomer of guanine.

Isothermal amplification Amplification of a nucleic acid sequence using a single temperature during the entire process.

Isotonic Of the same osmolality of body tissues, red blood cells, bacteria, etc.

Isotype (antibody) Five major types of antibodies found in the immune system based on heavy chain constant regions; IgG, IgM, IgE, IgE, and IgA.

K

Karyosome Dense mass of chromatin material inside a nucleus.

Keratitis Inflammation of the cornea.

KIA Kligler iron agar (tube).

Kinetoplast A mass of mitochondrial DNA that may be visible in some flagellated protozoans.

KOH See potassium hydroxide stain.

Kohler illumination Process of steps that ensures even illumination in bright-field microscopy.

Koplik spots White spots or patches inside the oral cavity associated with the rubeola (measles) virus.

L

Labialis Fluid-filled lesions or cold sores on the lips.

Laboratory developed tests (LDTs) A diagnostic test that has been designed and developed in the laboratory. The laboratory must demonstrate the performance characteristics and clinical efficacy of the test.

Laboratory information system (LIS) Computer system that is utilized within the laboratory that is capable of interfacing with instruments and the hospital computer system.

Lacrimal gland Paired exocrine glands that secrete tears.

Lag phase Period of slow microbial growth that occurs following inoculation of the culture medium. Organisms grow slow as they adjust to the changes in the nutrients, temperature, and osmotic pressure or other selective pressures in the medium.

Laked blood Hemolyzed blood; hemolysis may be affected in various ways, but alternate freezing and thawing is a simple method.

Laminar flow Nonturbulent flow of air in layers (flowing in a vertical direction in the case of a biosafety hood.)

Laryngitis Inflammation of the larynx.

Laryngotracheobronchitis Inflammation of the larynx, trachea, and bronchi.

Latent An infectious disease that is capable of latency remains in a dormant state within the host without apparent signs or symptoms. Latent infectious agents can reactivate and become active infections.

Lateral gene transfer Transfer of genetic material across from one cell to another, not due to normal cell growth and division. May be genetic transfer to another genus or species of microorganism or infectious agent.

Latex agglutination Agglutination of latex particles coated with antibody molecules when exposed to the corresponding antigen.

LCR Ligase chain reaction.

LDT See laboratory developed tests.

Lectin Naturally produced proteins or glycoproteins that can bind with carbohydrates or sugars to form stable complexes.

Legionnaires' disease Febrile and pneumonic illness caused by *Legionella* spp.

Leishman-Donovan (L-D) body Small, round intracellular form (called amastigote or leishmanial stage) of *Leishmania* spp. and *Trypanosoma cruzi*.

Lepromatous leprosy Disseminated leprosy.

Leprosy See Hansen disease.

Leukocytoclastic vasculitis Inflammation of the small blood vessels that is immune mediated. May also be called hypersensitivity vasculitis.

Leukocytosis Elevated white blood cell count.

Leukopenia Low white blood cell count.

LGV Lymphogranuloma venereum; the name for certain strains of *Chlamydia trachomatis* that cause a systemically expressed sexually transmitted disease.

Light microscopy (bright field) Microscope that uses visible light for detection. Items appear dark on a bright background.

Limit of detection (LOD) Lowest level an analyte can be detected in comparison to a negative sample.

Lipopolysaccharide Carbohydrate-lipid complex; integral substance in gram-negative cell walls. Also known as endotoxin.

Liposome Small, closed vesicle consisting of a single lipid bilayer.

Lipoarabinomannan (LAM) A glycolipid that is a major cell wall component in *Mycobacterium tuberculosis.*

Liquid phase extraction Nucleic acid purification completed by separating phases in solution and centrifugation. Often uses organic compounds for phase separation.

Livestock-associated infection (LAI) Infectious disease acquired through contact with livestock.

LOD See limit of detection.

Logarithmic phase Period of maximal growth rate of a microorganism in a culture medium.

L-phase Cells that form without cell walls.

LPS Lipopolysaccharide; see endotoxin.

Lysis Disintegration or dissolution of bacteria or cells.

Lysogenic Refers to the life cycle of a virus capable of lysogeny.

Lysogeny Viral genome integrated into that of its host bacterium resulting in replication of the virus through the replication and division of the host organism.

Lysosome Internal cellular–membrane-enclosed vesicle that contains digestive enzymes.

Lysozyme The enzyme, muramidase, produced in animals including humans that is capable of digesting cell wall components, peptidoglycan residues, in gram-positive and gram-negative bacteria.

M

MAC *Mycobacterium avium-intracellulare* complex.

Macrophage See monocyte.

Macroconidia Large, usually multiseptate, club- or spindle-shaped fungal spores.

Macrodilution (antibiotic susceptibility testing) Procedure is the same as determining minimum inhibitory concentration with a microdilution (0.05 to 0.1 mL of media) with a larger volume of media, usually 1 mL or greater.

Macules Small, round, flat color changes in the skin.

Magnification The measurement of enlargement for visualization of an object that can be completed using a microscope and various sets of lenses.

Maintenance medium Viral maintenance media is a liquid formula that is placed over cell cultures to maintain growth of the cells without initiating rapid growth; rapid growth also results in rapid death, which is undesirable in cell culture.

Major histocompatibility complex Large group of genes on the human chromosome that encodes for proteins on the surface of cells that play a role in recognition of self and nonself molecules.

Mammillated Covering that is rough or lumpy.

Mass spectrometry Method for determining composition of a substance by observing its volatile products during disintegration and comparing them with known standards.

Master mix See reaction mix.

Mastoidectomy Procedure that removes air from within the skull near the inner ear.

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) Ionization method that uses a matrix to absorb the laser energy, allowing the protein ions to escape.

Matrix protein Viral structural proteins that attach the viral envelope to the viral core proteins and stabilize the virion structure.

MBC Minimum bactericidal concentration.

McFarland standard 0.5 McFarland standard, which is commercially available, provides an optical density comparable to the density of a bacterial suspension of 1.5 × 108 CFU/mL.

Media, differential Media that incorporates a substrate and indicator system so that organisms possessing certain enzymes are recognized.

Media, enrichment Media that contain high levels of nutrients to enhance the growth of an organism or group of organisms.

Media, selective Culture media that contain inhibitory substances or unique growth factors such that one organism or organisms being sought will grow and prevent the growth of other types of organisms.

Mediastinum Space in the middle of the chest between the medial surfaces of the two pleurae.

Melena Feces that contains blood; appears dark and has a sticky consistency.

Melioidosis Disease caused by *Burkholderia pseudomallei*.

Melting temperature (Tm) The temperature is a calculated value based on the number of purines and pyrimidines. When applied to a double-stranded DNA, 50% of double-stranded DNA becomes single-stranded. Formula 2°C (#A+#T) + 4°C (#G + #C)

Meningitis Inflammation of the meninges, the membranes that cover the brain and spinal cord (e.g., bacterial meningitis).

Meningoencephalitis Concomitant meningitis that occurs with encephalitis (inflammation of the brain parenchyma).

Mesophilic An organism that prefers to grow in a temperature range generally between 20°C and 45°C.

Merogony Parasitic protozoan asexual reproduction via duplication of the nucleus.

Meront The form of a parasitic protozoan that undergoes reproduction or doubling of the nucleus and organelles of the cell.

Merozoite Product of schizogonic cycle in malaria that invades red blood cells.

Mesenteric adenitis Inflammation of mesenteric lymph nodes.

Mesentery A fold of the peritoneum that connects the intestine with the posterior abdominal wall.

Metabolic profile A series of biochemical reactions that are characteristic of a specific organism or group of organisms used for identification purposes.

Metacercariae A tailless, encrusted larva of a trematode.

Metacestode larvae Larval stage of a tapeworm found in an intermediate host.

Metacyclic Infective cycle of a trypanosome outside of the host.

Metastatic Spread of an infectious (or other) process from a primary focus to a distant one via the bloodstream or lymphatic system.

Metulae Outer branch of a fungus that is directly attached to the conidia.

MHA-TP Microhemagglutination test for antibody to *Treponema pallidum*.

MIC Minimum inhibitory concentration.

Microaerobic Requiring a partial pressure of oxygen less than that of atmospheric oxygen for growth. Refers to both capnophilic and microaerophilic organisms.

Microaerophilic Microorganism that grows under reduced O_2 (5% to 10%) and increased CO_2 (8% to 10%).

Microarray High throughput molecular diagnostic test that uses a solid surface coated with numerous nucleic acid sequences.

Microbiome The total populations of varying microorganisms that live in or on a host and do not cause harm. Considered normal flora, microbiota or indigenous flora provide protection to the host from other potentially invading pathogens.

Microbiota The microorganisms that are generally present as colonizers in and on the surface of living organisms. Considered normal or indigenous flora or resident microbiota. Prevent the colonization of the surfaces by other pathogenic microorganisms or infectious agents.

Microconidia Small, single-celled fungal spores.

Microdilution (antibiotic susceptibility testing) Determining the minimum inhibitory concentration of an antibiotic using a small media volume of 0.05 to 0.1 mL.

Microfilaria Embryos produced by filarial worms and found in the blood or tissues of individuals with filariasis.

Microforms Abnormally small yeast cells, ranging from 2 to 5 μm.

Microorganism-mediated resistance Acquired antimicrobial resistance because of mutational genetic events, gene exchange, or both.

Miliary Of the size of a millet seed (0.5 to 1.0 mm); characterized by the formation of numerous lesions of the above size distributed rather uniformly throughout one or more organs.

Minimum bactericidal concentration (MBC) The minimum concentration of antimicrobial agent needed to yield a 99.9% reduction in viable CFUs of a bacterial or fungal suspension.

Minimum inhibitory concentration (MIC) The minimum concentration of antimicrobial agent needed to prevent visually discernible growth of a bacterial or fungal suspension.

Miracidium Free-swimming, ciliated larval stage of a fluke.

Mixed culture More than one organism growing in or on the same culture medium and mixed within the colonies, as opposed to a single organism in pure culture or a pure colony.

Mobilome The set of mobile genetic elements within an organism's genome.

Mode of action Also known as mechanism of action; the biochemical interaction of the drug and the intended target.

Mode of transmission The means in which an individual encounters an infectious agent or microorganism.

Molecular sibling An organism that cannot be distinguished from another based on phenotypic, metabolic, and clinical presentations; it is recognized as a different species from its sibling based on molecular analysis.

Molecular weight size marker These are commercially prepared prestained or unstained proteins or nucleic acid markers of known sizes that are applied to electrophoresis to monitor the separation of the molecules and are used as comparative size markers based on migration distance.

Monocistronic Single gene or coding sequence.

Monoclonal antibody Antibody that is derived from a single cell producing one antibody molecule type that reacts with a single epitope.

Monocyte Mononuclear phagocytic cell present in the peripheral blood circulatory system that when activated by invasion of a foreign agent or microorganism, the cell moves toward the site of injury or infection and is a primary phagocyte known as a macrophage.

Monolayer A confluent layer of tissue culture cells one cell thick.

Monomicrobic Contains one single, specific organism.

Monozoic An oocyst that develops into a single sporozoite.

Mordant Chemical that combines with a dye or stain and fixes it within the material or cell.

Morphotype Group of bacteria that are distinguishable from others based on physical characteristics.

Morulae Cytoplasmic vacuoles containing enriched organisms.

MOTT Mycobacteria other than *Mycobacterium tuberculosis*.

Mucociliary escalator Ciliated cells that line the mucus membranes of the bronchi and trachea. Upward movement of cilia transfers infectious agents and particles trapped in mucus out of the lower lungs.

Mucopurulent Term used to describe material containing both mucus and pus (e.g., mucopurulent sputum).

Mucosa A mucous membrane.

Mucosa-associated lymphoid tissue (MALT) Areas of focused lymphoid tissue and cells throughout the body and associated with mucous membranes such as in the lungs.

Mucosal surface phagocytes (M cells) Macrophages and neutrophils that migrate to the mucosal surfaces.

Mucus Thick, sticky, gelatinous chemical naturally produced by the body that lines the sinuses, nose, mouth, throat, esophagus, and lungs. Contains chemicals such as digestive enzymes (i.e., lysozyme) and antibodies that protect the body from infecting microorganisms; it lubricates the membranes to keep them from drying.

Multilocular Multiple chambers.

Multiple myeloma Malignancy involving antibody-producing plasma cells.

Multiplex PCR A PCR reaction with more than one primer pair in the reaction mixture is used to amplify more than one target sequence, generally from multiple different organisms simultaneously.

Murein layer The peptidoglycan layer that consists of protein and sugar within the cell wall of bacteria.

Murein sacculus The entire composition of the peptidoglycan layer that surrounds the cell.

Mutagen A chemical or radiation that is capable of causing mutations in nucleic acids.

Mutation Change in the original nucleotide sequence of a gene or genes.

Mycelium Mass of hyphae making up a colony or visible structure of a fungus.

Mycetoma Chronic infection, usually of feet, caused by various fungi or by *Nocardia* or *Streptomyces*, resulting in swelling and sinus tracts; pulmonary mycetoma is a mass of fungal hyphae ("fungus ball") growing in a cavity formed during previous tuberculosis infection or other pathologic condition.

Mycolic acid Long-chain fatty acids found in the cell walls of *Mycobacterium* spp.

Mycoses Diseases caused by fungi (e.g., dermatomycosis, fungal infection of the superficial skin).

Mycotic aneurysm Bacterial infection causing inflammatory damage and weakening of an arterial wall.

Myocarditis Inflammation of the heart muscle.

Myositis Inflammation of a muscle, sometimes caused by infection, as in pyomyositis.

N

NAD See nicotinamide adenine dinucleotide.

Noncarriers An individual that is not colonized with any potential pathogenic microorganism.

Nares External openings of nose (i.e., nostrils).

Nasopharyngeal Pertaining to the part of the pharynx above the level of the soft palate.

Natural killer cells (NK cells) Type of lymphocyte (white blood cell) that is part of the innate or natural nonspecific immunity. The cells destroy tumor cells and virally infected cells.

Necrosis Pathologic death of a cell or group of cells.

Necrotizing fasciitis A very serious, painful infection involving the fascia (membranous covering) of one or more muscles; may spread widely in short periods since there is no anatomic barrier to spread in this type of infection.

Negative control A standardized sample used in a diagnostic assay or test that is reproducible and consistently demonstrates a negative result in the assay.

Negative validation testing Method used to compare a validation of a test to invalid data.

Negri bodies Inclusion bodies found in nerve cells infected with the rabies virus.

Neonatal First 4 weeks after birth.

Nephelometry Measurement of turbidity where the photometer is placed at angles to the suspension, and the scattered light, generated by a laser or incandescent bulb, is measured.

Nested PCR A PCR assay that involves the sequential use of two primer sets, with one set inside the other, amplifying internal sequence within the first amplicon.

Neuraminidase (NA) Viral protein of influenza virus. Cleaves sialic acid residues in mucus, permitting the virus to attach, and assists in releasing the virus from infected cells.

Neurotrophic Having a selective affinity for nerve tissue.

Neutrophil (PMN, polymorphonuclear cell) A white blood cell that contains a multilobed nucleus. The cell is considered the first responder to any break or penetration of barriers to infection. The cell is a nonspecific phagocyte.

Next-generation sequencing (NGS) High-throughput DNA sequencing that uses parallel processing of amplified DNA templates in separated chambers.

NGU Nongonococcal urethritis.

Nicotinamide adenine dinucleotide (NAD) Metabolic cofactor used in energy-generating pathways.

Nick translation Use of enzymes to break DNA and repolymerize small sections of the molecule, usually to label the DNA with a radioactive nucleotide.

Nocturnal Active during the nighttime.

Nomenclature Naming of microorganisms according to established rules and guidelines. Also, see binomial nomenclature.

Nonphotochromogen Slow-growing, nonpigmented mycobacteria independent of light conditions.

Nonseptate See aseptate.

Nonspecific immune defense mechanisms Physical or chemical attributes of the human structure or function that are not directed at a specific infectious agent. Considered part of the natural innate immune system.

Nontuberculous mycobacteria (NTM) All species of mycobacteria that do not belong to *Mycobacterium tuberculosis* complex.

Normal flora See microbiota.

Northern blot Separation of RNA using electrophoresis followed by transfer to a solid membrane surface and detected using a labeled complementary nucleic acid probe.

Nosocomial Pertaining to or originating in a hospital or other health care facility, for example, nosocomial infection also referred to as health care–associated or acquired infection.

Nucleic acid hybridization Process by which the single-stranded nucleic acid fragment or probe unites (hybridizes) with complementary DNA.

Nucleic acid probe Piece of labeled single-stranded DNA used to detect complementary nucleic acid in clinical material or a culture that specifically identifies the presence of the sequence in the material.

Nucleocapsid Virus nucleic acid core enclosed in the protein capsid coat.

Nucleoid Genetic material of a prokaryotic cell; generally, centrally located.

Nucleoprotein Protein complex with nucleic acid.

Nucleotide Contains a nucleoside (which is a sugar), a nitrogenous base, and a phosphate that make up the building blocks of nucleic acids.

Nucleus Membrane-bound structure that encloses the nucleic acid genome in eukaryotic cells.

Nutritive media Media that support the growth of a wide range of nonfastidious microorganisms and are considered nonselective.

O

Octal numbers Numbers used in computer databases to identify biochemical profiles of organisms and thus their identification.

O-F Oxidation-fermentation medium. Paired set of tubes that contains a carbohydrate. One tube is overlaid with oil to produce anaerobic conditions, and the other is left open to atmospheric oxygen. Differentiates an organism's ability to oxidize or ferment the carbohydrate.

Oil immersion Use of immersion oil to fill the space between the slide being studied and the special objective (oil immersion lens) of the microscope; this keeps the light rays from dispersing and provides good resolution at high magnification (total magnification of 1000×).

Oligonucleotide probe See probe.

Oncogenic Possessing the potential to cause normal cells to become malignant; causing cancer.

Oncosphere Larval form of a tapeworm found in the intermediate host.

Oncovirus Virus capable of causing cancer.

ONPG O-nitrophenol-β-galactopyranoside (β-galactosidase test).

Onychomycosis Infection of the nail and nail bed and surrounding tissue.

Oocyst A cyst that contains a diploid zygote from a protozoan.

O&P Ova and parasite examination. Includes three parts, a wet mount, concentration, and a smear that is permanently stained for detection and detailed identification of parasites from fecal samples.

Operator region Region of a sequence of genes or operons that lie within the promoter region and controls transcription by the binding of a regulatory protein.

Operculated ova Ova possessing a cap or lid.

Operculum The cap or lid of a parasitic egg or ovum.

Operon A set of genes in a prokaryotic cell that are controlled by one promoter and function as a set of products that work together.

Opportunistic infection An infection caused by an opportunistic pathogen.

Opportunistic pathogen Organism that does not normally cause disease or damage in a host, but under specific conditions or opportunities causes pathology or disease.

Opsonize (opsonization) To facilitate destruction of pathogens by phagocytic ingestion or lysis by complement through the action of coating antibodies or complement fragments.

Optical density A measurement of turbidity.

Oral cavity The oral cavity includes the mouth, the buccal mucosa (lining inside of the mouth), the palate (bony roof of the mouth), the tongue, and the floor of the mouth underneath the tongue.

Origin of replication Specific sequence on a segment of a chromosome where replication begins.

Orolabial Mouth and lips.

Osteomyelitis Inflammation of the bone and the marrow.

Otitis Inflammation of the ear from a variety of causes, including bacterial infection; otitis media is inflammation of the middle ear.

Otomycosis Fungal ear infection.

Ovum Female reproductive cell or egg.

Oxidation A metabolic pathway of the microorganism that involves use of oxygen as a terminal electron acceptor.

Oxidation-reduction potential Electromotive force exerted by a nonreacting electrode in a solution containing the oxidized and reduced forms of a chemical, relative to a standard hydrogen electrode; the more negative the value, the more anaerobic conditions are.

Oxidative phosphorylation Metabolic pathways that utilize oxygen to add phosphates to organic molecules resulting in energy rich molecules to fuel cellular processes.

Oxidizing (chemical) Chemical that can accept electrons from another chemical.

Ozena Chronic nasal drainage (rhinitis); may be accompanied with cellular destruction.

P

Palindromic sequence A sequence of a nucleic acid that reads the same in the forward and reverse direction.

Pandemic Epidemic over a wide geographic area, or even worldwide.

Papilla A bump or protrusion that extends from a plant, fungus, or tissue.

Papules A slightly elevated red rash that contains no fluid.

Paracentesis Surgical transcutaneous puncture of the abdominal cavity to aspirate peritoneal fluid.

Parafungal Organisms that resemble fungi but have characteristics of protozoans.

Parasite Organism that lives on or within and at the expense of another organism.

Paratenic Not required for the development or life cycle of the parasite.

Parenchymatous Soft cellular tissue.

Parenteral Route of administration of a drug other than by mouth; includes intramuscular and intravenous administration.

Paronychia An infection of the tissues surrounding the nails.

Par otitis Inflammation of the parotid gland, the largest of the salivary glands; mumps is the most common cause of this.

Paroxysm Rapid onset (or return) of symptoms; term usually applies to cyclic recurrence of malaria symptoms, which are chills, fever, and sweating.

Paroxysmal stage Stage of pertussis that is evident by violent coughing with a characteristic whooping sound.

Parthenogenesis A form of asexual reproduction in which growth and development occur without fertilization.

Passive immunization Immunization that is a result of passively providing either antibodies or cells from another immune individual.

Pasteurization Heating a substance to remove pathogenic organisms without removing all organisms within a food; extends the shelf life of the food.

Pathogen Microorganism that causes infection and/or disease.

Pathogenesis The process or development of disease.

Pathogenic Producing disease.

Pathogenicity The ability of an organism or infectious agent to produce disease.

Pathogenicity islands Stretches of DNA that contain genes associated with bacterial virulence and are absent in avirulent or less virulent strains of the same species.

Pathologic Caused by or involving a morbid condition, as a pathologic state.

Pauciseptate Few or sparsely septate cross walls.

PCR See polymerase chain reaction.

Peak level The highest concentration a drug or antimicrobial can reach in the patient's blood.

Peliosis Proliferation of small blood capillaries and spaces that fill with blood in a specific organ or tissue.

Penicillin-binding protein Enzymes essential for bacterial cell wall production, trans peptidases. When bound by penicillin, cell wall synthesis stops.

Penicillinase (β-lactamase) Enzyme produced by some bacterial species that inactivates the antimicrobial activity of certain penicillins (e.g., penicillin G).

Peptide nucleic acid probe (PNA) Synthetic nucleic acids that have replaced the negatively charged sugar-phosphate backbone of DNA with a neutral polyamide backbone.

Peptidoglycan Bacterial cell wall or murein layer that gives the bacterial cell shape and strength to withstand changes in environmental osmotic pressures.

Peracetic acid (chemical disinfectant) (0.23%) combined with hydrogen peroxide, effective for removal of contamination when organic material such as blood or body fluids are present.

Percutaneous Performed through the skin (e.g., percutaneous bladder aspiration).

Pericarditis Inflammation of the covering of the heart (pericardium).

Perineum The portion of the body bound by the pubic bone anteriorly, the coccyx posteriorly, and the bony prominences of the ileum on both sides.

Periodic acid–Schiff (PAS) stain Method of staining that relies on a specific reaction known as the Schiff reaction used to stain polysaccharides, glycogen, glycoproteins, and glycolipids in tissue or cells.

Periodicity A recurring cycle that has a specific pattern.

Periplasmic space Space between the inner cellular membrane and the outer membrane of a gram-negative microorganism.

Peritoneal cavity Space between the visceral and parietal layers of the peritoneum.

Peritoneum Large, moist, continuous sheet of serous membrane lining the abdominal pelvic cavity and the outer coat of the organs contained within the cavity.

Peritonitis Inflammation of the peritoneal cavity, most often caused by bacterial infection.

Pernicious anemia A decrease in red blood cells due the body's inability to absorb or a decrease in vitamin B_{12} (deficiency).

Persistent carrier An individual that is colonized with a single strain of a potential pathogenic microorganism for an extended period.

Persister cells Microbial cells that are deep within a bacterial biofilm that display reduced metabolism and a higher level of antibiotic resistance.

Personal protective equipment (PPE) Protective equipment that is worn to avoid infection, including gowns, gloves, mask, respirators, and other more advanced equipment based on the degree of infectious agent.

Pertussis Upper respiratory infection characterized by a sustained cough primarily caused by *Bordetella pertussis*.

Petechiae Tiny hemorrhagic spots in the skin or mucous membranes.

PFGE See pulsed-field gel electrophoresis.

Phaeohyphomycosis Term used to describe any infection caused by a dematiaceous organism.

Phagocyte A type of white blood cell that can engulf bacteria and other particles in the body and digest and remove them.

Phagocytosis Process of ingesting cells.

Phagolysosome A membrane-enclosed structure within a cell, following the fusion of a phagosome and lysosome, which functions in the digestion and removal of foreign materials.

Phagosome Internal vesicle that contains foreign material within a phagocytic cell.

Phase-contrast microscopy Technique for direct observation of unstained material in which light beams pass through the object to be visualized and are partially deflected by the different densities of the object. The light beams are deflected again when they impinge on a special objective lens, increasing in brightness when aligned in phase.

Phenolic (chemical disinfectant) Derivatives of carbolic acid (phenol) such as *ortho*-phenylphenol and *ortho*-benzyl-*para*-chlorophenol. Effective in killing all types of microorganisms but is not considered sporicidal (it is unable to destroy endospores).

Phenotype Pattern of characteristics of an organism beyond the genetic level that includes readily observable features.

Phenotypic A characteristic that is observable.

Phialide Projection of a fungus that is directly attached to the conidia or reproductive spores.

Photo bleaching Fading or the permanent loss of fluorescence because of chemical damage to the fluorochrome.

Photochromogen Mycobacteria that produce pigment after exposure to light but whose colonies remain buff-colored in the dark.

Photometer Instrument that converts the light that impinges (strikes) the surface of a detector and converts the interaction to an electrical impulse, which can be quantified.

Phycomycosis Serious infection involving fungi, often beginning with necrotic lesions in the nasal mucus or palate but rapidly spreading to involve other tissues. Seen in immunocompromised patients.

Phylogeny Subdivision of biology that characterizes and separates organisms based on evolutionary relatedness.

PID Pelvic inflammatory disease.

Pili Structures in bacteria similar to fimbriae that participate in bacterial conjugation and transfer of genetic material.

Planktonic Free-living organisms that float in a liquid environment or body of water; organisms do not live attached to surfaces.

Plasma Fluid portion of blood; obtained by centrifuging anticoagulated blood.

Plasma cell An activated B cell that produces antibodies.

Plasmids Extrachromosomal DNA elements of bacteria carrying a variety of determinants that may permit survival in an adverse environment or successful competition with other microorganisms of the same or different species.

Plateau phase The final phase of PCR when no additional products are being produced and all the reaction components are used up.

Pleomorphic Having more than one form or shape, usually widely different forms, as in pleomorphic bacteria that microscopically may appear as both cocci and rods in the same sample.

Plerocercoid Larvae of tapeworms, generally the infective stage of an intermediate host.

Pleura The serous membrane enveloping the lung and lining the internal surface of the thoracic cavity.

Pleural empyema Foci or collection of pus and microorganisms in the pleural cavity.

PMN See neutrophil.

PNA See peptide nucleic acid probe.

Pneumolysin Bacterial cholesterol-dependent exotoxin that forms pores in the membranes of human cells inducing further cellular damage and cell lysis.

Pneumonia Inflammation of the lungs, primarily caused by infectious agents.

Pneumonic plague Respiratory form of an infection with *Yersinia pestis.*

Pneumothorax Introduction of air (usually inadvertently) into the pleural space, leading to collapse of the lung on that side.

Poisonous (chemical) Capable of causing serious illness and death.

Polar filament Filament or tubule in a spore or egg of a parasite that is used to penetrate a host cell.

Polar tubule See polar filament.

Polycistronic A nucleic acid sequence that encodes an mRNA, which contains more than one gene or cistron in a single molecule.

Polyclonal antibody Collection of antibodies made by multiple B cell lineages to the same antigen.

Polymerase An enzyme that makes a polymer of nucleic acid; DNA polymerase or RNA polymerase.

Polymerase chain reaction (PCR) A method for expanding small discrete sections of DNA by binding DNA primers to sections at the ends of the DNA to be expanded and using cycles of heat (to create single-stranded DNA) and cooler temperatures (to allow a DNA polymerase enzyme to create new sections of DNA between the primer ends).

Polymicrobic Contains more than one specific type or species of microorganism.

Polymorphic An organism with more than one life cycle form or cellular shape.

Polymorphonuclear cell See neutrophil.

Polyphasic taxonomy Classification of organisms using a complex analysis of the ribosomal ribonucleic acid (rRNA) sequences, whole genome sequences, epigenetics, and mass spectrometry. This includes mechanisms of control, regulation, transcription, and translational products.

Polysome A messenger RNA that contains multiple ribosomes all simultaneously translating proteins.

Polyvinyl alcohol (PVA) Used as a preservative for stool (fecal) specimens in clinical microbiology to maintain the structure of parasites.

Porin Membrane proteins or pores found in the outer membrane of gram-negative organisms.

Positive control A standardized sample used in a diagnostic assay or test that is reproducible and consistently demonstrates a positive result in the assay.

Post-herpetic neuralgia Burning pain in the nerves following shingles.

Posttranscriptional regulation Regulation of gene expression at the RNA level, prior to translation.

Posttranslational modification Modification of a protein following translation includes adding chemical groups such as phosphates, methyl groups, or others.

Post zone High antigen concentration that results in all antigen-binding sites of available antibodies bound to antigen preventing cross-linking or lattice formation.

Potassium hydroxide stain (KOH) A solution of potassium hydroxide that is used to break up the keratin in tissue cells releasing fungi, in order to visualize them microscopically.

PPD Purified protein derivative (skin test antigen for tuberculosis).

Precipitin test Detection of antigen by allowing specific antibody to diffuse through liquid or gel until an antigen-antibody complex forms; this complex is visualized as a line of precipitated material.

Precision Reproducibility of a test when run several times.

Prepuce Foreskin.

Prevalence Frequency of disease in a population at a given time.

Primary amebic meningoencephalitis (PAM) Fatal infection caused by the free-living ameba *Naegleria fowleri.*

Primary antibody response The first encounter with an antigen that results in the production of antibodies. The classic primary antibody response is predominantly IgM with low levels of IgG.

Primary culture The initial culture from a specimen on a battery of media based on the site of infection used for additional testing for organism identification and antimicrobial susceptibility testing.

Primary plate reading Examining the primary culture battery of media used for identification of an organism. Requires correlation of the morphological characteristics and biochemical characteristics of the isolates to direct Gram stains from the primary specimen and the site of infection.

Primary stain The first stain that is applied to a microscopic smear of an organism in a complex differential stain followed with a decolorization of the smear and application of a secondary stain.

Primer extension See extension.

Primers A single-stranded nucleic acid sequence or oligonucleotide used for the initiation of DNA synthesis in an amplification assay. Two primers, a forward and a reverse, are required to complete the synthesis of a double-stranded amplicon.

Prion Proteinaceous infectious agent associated with Creutzfeldt-Jakob disease and perhaps other chronic, debilitating central nervous system diseases.

Probe A single-stranded nucleic acid sequence or oligonucleotide that is conjugated with a label and used to detect a specific nucleic acid sequence in a molecular assay by hybridizing to the complementary target.

Proboscis Tubular appendage on the scolex of a tapeworm.

Procercoid The first larval stage of a tapeworm that develops within a copepod.

Proctitis Inflammation of the rectum.

Prodromal Early manifestations of a disease before specific symptoms become evident.

Proglottid Segments of the tapeworm containing male and female reproductive systems; may be immature, mature, or gravid.

Prognosis Forecast as to the possible outcome of a disease.

Prokaryotic Organisms without a true nucleus.

Promastigote Life cycle stage of some flagellated protozoans that has a single anterior flagellum and lacks an undulating membrane.

Promoter A region in a DNA sequence where initiation of transcription begins.

Prophylaxis Preventive treatment (e.g., the use of drugs to prevent infection).

Prostatitis Inflammation of the prostate gland, usually caused by infection, characterized by fever, low back or perineal pain, and at times urinary frequency and urgency; a common background factor for recurrent cystitis in males.

Prosthesis An artificial part such as a hip joint or eye.

Protein A A protein on the cell wall of strains of *Staphylococcus aureus* (Cowan strain) that binds the Fc portion of antibodies.

Prototroph Naturally occurring or wild strain.

Prozone High concentration of antibody versus antigen resulting in failure to cross-link; may result in false negatives.

Pseudohyphae Extensions from yeast that are irregular, sausage-shaped cells with constrictions evident.

Pseudomembrane Necrosis of mucosal surface simulating a membrane.

Pseudomembranous colitis (PMC) Syndrome in the large bowel characterized by a layer of necrotic tissue and dead inflammatory cells often caused by the toxin of *Clostridioides difficile*.

Pseudopodia Extension from an amoeboid cell that pulls the cell for movement.

Psittacosis Zoonotic disease caused by *Chlamydia psittaci.*

Psychrophilic Cold loving (e.g., microorganisms that grow best at low [4°C] temperatures).

Pulsed-field gel electrophoresis (PFGE) Electrophoretic method that separates large fragments of nucleic acid though an agarose matrix with alternating pulses of current in an electrical field.

Pure colony A single bacterial or fungal colony on artificial media that is a result of separation and arises from a single cell.

Purine A double ring compound that is composed of carbon and nitrogen. The purines consist of adenine and guanine and are used in the synthesis of DNA and RNA, as well as other high-energy molecules ATP and guanosine triphosphate (GTP).

Purulent Consisting of pus.

Pus Product of inflammation, consisting of fluid and many white blood cells; often bacteria and cellular debris are also present.

Pustule Containing purulent material consisting of necrotic inflammatory cells.

Pyelonephritis Infection of the kidney and renal pelvis and the late effects of such infection.

Pyocin Pigment produced by a bacterium that has antibacterial properties against other strains or species of bacteria.

Pyogenic Pus-producing.

PYR test The enzyme, l-pyroglutamyl-amino peptidase, hydrolyzes l-pyrrolidinyl-β-naphthylamide (PYR) to produce β-naphthylamine. When the β-naphthylamine combines with cinnamaldehyde reagent, a red color is produced.

Pyriform Pear-shaped.

Pyrimidine A single ring compound that is composed of carbon and nitrogen. The purines thymine and cytosine are used in the synthesis of DNA; uracil and thymine are used in the synthesis of RNA.

Pyridoxal Active form of vitamin B_6.

Pyrogenic Fever-inducing.

Pyrosequencing Method that incorporates a luminescent signal (generation of a pyrophosphate) when nucleotides are added to the growing nucleic acid strand. The release of the pyrophosphate during extension is converted to ATP, which is then used in a chemical reaction to release a chemical signal for each nucleotide. The amount of light is proportional to the amount of the specific nucleotide.

Pyuria Presence of eight or more leukocytes per cubic millimeter on microscopic examination of uncentrifuged urine.

Q

QC Quality control.

Q fever Disease caused by the organism *Coxiella burnetii.*

QNS Quantity not sufficient.

Quaternary ammonium compounds (chemical disinfectant) Quaternary ammonium compounds utilize cationic detergents to disrupt the cellular membranes of microorganisms and other organic cells.

Quencher Molecule that can accept energy from a fluorophore and then dissipate the energy so that no fluorescence results.

Quenching The transfer of the light energy to nearby molecules in the sample such as free radicals, salts of heavy metals, or halogens.

Quorum sensing Bacteria produce a variety of molecules when they are multiplying. In this process, they release chemicals that are sensed by the organisms around them. Once they reach a critical mass, the signal up-regulates or down-regulates specific genes to enhance survival of the organism.

R

Radioisotope Unstable molecule that emits detectable radiation (e.g., gamma rays, x-rays) for a known period (half-life). Can be incorporated into other compounds as a label for later detection by radiographic film exposure or by measurement in a scintillation-counting instrument.

Rapid-growing mycobacterium (RGM) Growth is apparent sooner than 7 days after subculture to Lowenstein-Jensen medium.

Rat-bite fever Zoonotic disease caused by *Streptobacillus moniliformis* or *Spirillum minus.*

Reaction mix Also referred to as master mix.

Reagin A nonspecific antibody that is produced in syphilis and hypersensitivity reactions.

Real-time PCR (RT-PCR) A nucleic acid amplification method that uses the incorporation of a fluorescent signal into the amplicon for direct detection during the assay, in real time. May be qualitative or quantitative.

Recrudescence Recurrence of symptoms.

Redia Cylindrical larvae of a trematode.

Reiter syndrome Autoimmune disease that arises following an infection.

Replication fork The area of DNA synthesis where the two strands of a double helix are unwound, and active replication is in progress.

Reporter molecule A dye or molecule attached to a probe to detect the specific target sequence.

Repression The act of shutting off gene transcription, generally by an end-product feedback mechanism.

Repressor A protein that binds to DNA or RNA, inhibiting the expression of a gene at the transcriptional or translational level.

Reservoir Source, organism, environment, or place of origin from which an infectious agent may be disseminated; for example, humans are the only reservoir host for *Mycobacterium tuberculosis.*

Resident microbiota See microbiota.

Resin Plant product composed largely of esters and ethers of organic acids and acid anhydrides.

Resolution The extent to which detail in the magnified object is maintained.

Resolving power Characteristic of a microscope that is defined as the least distance between two objects that when magnified still allows the two objects to be distinguished from each other.

Restriction endonuclease Enzyme that breaks nucleic acid (usually DNA) at only one specific sequence of nucleotides.

Restriction fragment length polymorphism (RFLP) A technique that uses restriction endonucleases to produce fragments of nucleic acids that are separated by electrophoresis to identify the different patterns produced by the fragments or fingerprint of the organism.

Restriction site Also referred to as recognition site or restriction endonuclease site.

Reticulate body The metabolically more active form of elementary bodies of *Chlamydia* spp.

Reticuloendothelial system Macrophage system, which includes all the phagocytic cells of the body except for the granulocytic leukocytes.

Retroinfection Larva from an *Enterobius* spp. migrate into the anus increasing the level of infection.

Retrovirus An RNA virus that replicates by transcribing from RNA to DNA and then back to RNA. The initial replication enzyme is reverse transcriptase.

Reverse algorithm A method used to diagnose syphilis that begins and ends with a specific syphilis serology test, in place of beginning with a nonspecific screening test.

Reverse transcription Synthesis of DNA from RNA by using the enzyme reverse transcriptase.

Reverse transcription PCR (RT-PCR) A target sequence amplification reaction that begins with RNA and using a reverse transcription enzyme, synthesizes a complementary DNA sequence or amplicon.

RFLP See restriction fragment length polymorphism.

Rhabditiform larvae Nematode larvae that are passed from a definitive host.

Rheumatoid factor IgM antibodies produced by individuals against their own IgG.

Rhinitis Inflammation in the nasal cavity or nose.

Rhinoscleroma Granulomatous (forms masses of immune cells) bacterial infection of the nose.

Rhinorrhea Runny nose.

Ribonucleic acid (RNA) Nucleic acid molecule composed of adenine, guanine, cytosine, and uracil that is generally single stranded and includes messenger RNA (mRNA), transfer RNA (tRNA), ribosomal RNA (rRNA), noncoding RNA (ncRNA), microRNA (miRNA), small regulatory RNA (sRNA).

Ribosome Complex of RNA and proteins that bind mRNA and tRNA to process protein translation in a cell.

Ribotyping A molecular method that uses specific ribosome sequences to place organisms in taxonomic groupings.

Residual body Vesicles of indigestible material in macrophages removed from the cell by exocytosis.

Rhabditoid larvae See rhabditiform larvae.

Rhizoid Fine tubular growth from the stolon or hyphae of a fungus, that appears rootlike.

RNA See ribonucleic acid.

RNase Ubiquitous and stable enzymes that are capable of digesting RNA.

RNase H An enzyme, ribonuclease H, that degrades RNA when it is hybridized to a complementary DNA sequence.

Roseola A mild rash that may include fever caused by herpes viruses.

Rostellum Conelike protrusion from the scolex on the anterior end of a tapeworm. May be armed with hooklets or be unarmed (no hooklets).

RPR Rapid plasma reagin; nontreponemal test for antibodies developed in response to syphilis infection.

RT-PCR See real-time PCR or reverse transcription PCR.

Rugose Fungal colonial morphology characterized by furrows that radiate out from the center.

Saccharolytic Capable of breaking down sugars.

Safety data sheets (SDS) Previously known as material safety data sheets. Provided by manufacturers for chemicals and reagents that include health and safety precautions, storage, and disposal, as well as emergency information if the material is hazardous.

Salpingitis Fallopian tube inflammation.

Sandwich hybridization Also referred to as a capture probe with a detection probe. The first nucleic acid probe is attached to a solid support and captures the target nucleic acid, followed by hybridization of the second detection probe for identification.

Saprophytic Organisms that obtain nutrients by living on dead organic matter.

SBT See serum bactericidal testing.

Scalded skin syndrome A systemic disease caused by *Staphylococcus aureus* exfoliative toxin (serine protease) producing strains that result in systemic peeling of the skin. Due to systemic damage, patients are highly susceptible to other secondary bacterial infections.

Schizogony Stage in the asexual cycle of the malaria parasite that takes place in the red blood cells of humans.

Schizonts Sporozoites are transmitted from the mosquito vector of the malarial parasite, which mature into schizonts. Schizonts feed on the hemoglobin in the red blood cells.

Schlichter test Synonym for the serum bactericidal level test.

Schüffner dots Round, generally uniform red dots observed in red blood cells infected with malarial species.

Sclerotia A hard mass of mycelium.

Sclerotic Hard, indurated.

Scolex (plural Scolices) Head portion of a tapeworm; may attach to the intestinal wall by suckers or hooklets.

Scotochromogen Pigmented *Mycobacteria* spp. independent of light or dark exposure.

Scutula A mass of hyphae and spores that form a cup-shaped structure.

SCV See small colony variant.

Sebum Oil secreted from the sebaceous glands of the skin to moisten the skin to prevent drying.

Secondary antibody response See anamnestic response.

Secondary stain Used in a differential staining technique. The second dye applied following a decoloration step. Part of staining methods that use two dyes, used to differentiate organisms based on specific structural characteristics.

Selective media Support the growth of one group of organisms but not another organism by adding antimicrobials, dyes, or alcohol or other inhibitory chemicals to a medium.

Semiconservative replication Replication of DNA that begins with two parent strands. Each strand is used as a template to create a complimentary daughter strand; this results in two duplexes that are composed of one parent and one daughter strand.

Semiquantitative culture (isolation) A technique that provides an approximate quantity of colony forming units by either using a calibrated loop or streaking for isolation and estimating colony count based on quadrants.

Semisolid media Bacterial media that contain a lower concentration of agar than solid media. Generally used to visualize the motility of organisms by observing the growth as it moves through the semisolid mixture.

Senescent Aging.

Sense strand The strand of nucleic acid in a double-stranded DNA molecule that encodes the translatable sequence in the 5 to 3 prime orientation.

Sensitivity Ability of a test to detect (the microorganism, nucleic acid, or other compound) all true cases of the condition being tested for (patient displays signs and symptoms of infectious disease); absence of false-negative results. May also be referred to as analytical sensitivity. (Also see specificity.)

Sepsis A systemic inflammatory reaction caused by microorganisms in the bloodstream that may cause organ damage resulting in death.

Septate Having cross walls.

Septic shock Acute circulatory failure caused by toxins of microorganisms; often leads to multiple organ failure and is associated with a relatively high mortality.

Septicemia Systemic disease associated with presence of pathogenic microorganisms that are multiplying or their toxins are in the blood.

Septum (plural Septa) Single cross wall found in yeast or fungi.

Serology Study or diagnostics that utilizes serum and examines the interactions of antibodies and antigens.

Serosanguineous Like serous but with some blood present grossly.

Serous Like serum.

Serotype A strain of a microorganism that can be differentiated based on antigen types using specific antibodies.

Serpiginous A skin lesion that appears as a wavy line.

Serum Cell- and fibrinogen-free fluid remaining after whole blood clots.

Serum bactericidal testing (SBT) Lowest dilution of a patient's serum that kills a standard inoculum of an organism isolated from that patient; it is related to antibiotic level achieved in the patient's serum and the bactericidal activity of the drug.

Sessile Organisms that grow permanently attached to a substrate surface.

Sheath The outer covering present on some microfilariae, that is, the egg membrane. Unsheathed microfilariae rupture the egg membrane during development and are not sheathed.

Shell vial Small vials that contain a coverslip covered with a monolayer of cells. The cells are inoculated by centrifuging the sample, bringing the potential virus in close contact with the cells.

Shine-Dalgarno sequence Ribosomal binding site upstream of the start codon for protein translation in bacteria.

Shingles Reactivation of chicken pox. Develops a red rash that generally follows major nerve lines.

Sigma factor Accessory protein that is required and binds to the RNA polymerase to recognize the start site for transcription in bacteria.

Signal amplification A method in nucleic acid detection where the signal is enhanced using branched repeating structures and the target is not amplified.

Signs Observable and measurable physiological changes during an infection or disease.

Simple stain A single dye that is applied to a structure on a microscopic smear to improve contrast.

Simple transposon See insertion sequence.

Sinus Suppurating tract; paranasal sinus, hollows, or cavities near the nose (e.g., frontal and maxillary sinuses).

Sinusitis Inflammation of the mucous membranes of the sinuses.

Skin-associated lymphoid tissue (SALT) Immune surveillance-specific cells that are localized within the layers of the skin, including keratinocytes, Langerhans cells, and immunocompetent lymphocytes.

Skin colonizers Generally considered normal microbiota of the surface of the skin. Protect against invading pathogens and do not harm the host.

Slant See definition of "butt." The slant is the upper surface of the artificial solid medium in the tube and is exposed to air.

Slime layer Loose layer of extracellular polysaccharide and proteins that surround a bacterial cell.

Slow-growing mycobacteria (SGM) Require more than 7 days to produce colonies on solid media such as Lowenstein Jensen.

Small colony variant (SCV) Morphological variants of a microorganism that are generally slow-growing subpopulations of a bacterium. They are often resistant to antibiotics and have different phenotypic characteristics.

Sodium polyanethol sulfonate (SPS) Anticoagulant typically found in blood culture media.

Sodoku Zoonotic disease caused by the gram-negative bacterium *Spirillum minus.*

Solid phase extraction A method of extraction for nucleic acids from a sample that uses a solid support column constructed of fibrous or silica matrices, magnetic beads, or chelating agents to bind the nucleic acids.

Solid-phase immunosorbent assay (SPIA) ELISA test in which the captured antigen or antibody is attached to the inside of a plastic tube or microwell, or to the outside of a plastic bead, in a filter matrix, or some other solid support. Allows faster interaction between reactants and more concentrated visual products than ELISA tests performed in liquid.

Somatic Pertaining to the body (of a cell) (e.g., the somatic antigens of *Salmonella* spp.).

Somnolence Feeling drowsy and persistent sleepiness.

Southern blot Also referred to as Southern hybridization. Identification of specific genetic sequences by separating DNA fragments by gel electrophoresis and transferring them to membrane filters *in situ*. Labeled complementary DNA applied to the filter binds to homologous fragments, which can be identified by detecting the presence of the labeled DNA in association with bands of certain molecular size. Named after its discoverer, E.M. Southern.

Spargana White, wrinkled, and ribbon-shaped larvae of the parasite *Spirometra* spp.

Sparsely Small numbers.

Specialized transduction The movement of genetic material that is always connected to the same sequence in the genome from a host cell to another via a bacteriophage or virus.

Specific immune defense mechanisms Functions within the immune system that require a direct interaction and recognition of an antigen that results in the production of a targeted, specific immune response. May result in the production of immune memory.

Specificity Ability of a test to correctly yield a negative result (detect no microorganism, nucleic acid, or other compound) when the condition being detected, or the disease, is absent; absence of false-positive results. May also be referred to as analytical specificity. (Also see sensitivity.)

Spectrum of activity The type of microorganism or bacteria that an antimicrobial does and does not have the ability to affect by either slowing the growth or killing the microorganism.

Spikes A protein extension on a viral capsid or envelope that interacts with the receptor on the host cell that mediates binding and entry into the host cell.

Spiral groove Runs laterally across the posterior end of the parasite *Chilomastix mesnili*, giving the organism a curved posterior that assists the organism during movement.

Spongiform encephalopathies A degenerative brain disorder that is associated with prion disease, where the brain appears with holes like a sponge.

Sporangiophore The entire fungal reproductive structure, including the stalk, sporangium, and sporangiospores.

Sporangiospores Fungal spore that is produced and enclosed within a sporangium.

Sporangium A saclike structure produced at the tip of a long stalk, the sporangiophore.

Spore Reproductive cell of bacteria, fungi, or protozoa; in bacteria, may be inactive, resistant forms within the cell.

Sporocyst The zygote (diploid) stage of a parasite.

Sporogony The asexual reproductive process that results in the formation of sporozoites in parasites.

Sporont Sexual reproductive structure that is diploid but undergoes division known as sporogony for sporozoites.

Sporoplasm Structure of protoplasm that is used to form a spore in the Class Microsporidia.

Sporozoite Slender, spindle-shaped organism that is the infective stage of the malarial parasite; it is inoculated into humans by an infected mosquito and is the result of the sexual cycle of the malarial parasite in the mosquito.

Sputum Material discharged from the surface of the lower respiratory tract air passages and expectorated (or swallowed).

Squash (crush) prep Compressing a microscope slide on the top of another microscope slide that has a tissue or granular specimen and then spreading it with the secondary slide.

Standard precautions (universal precautions) Infection control guidelines used in the care of all patients; they apply to blood, body fluids, and secretions and excretions except sweat.

Start codon The first set of three nucleic acid bases at the beginning of an mRNA where translation of the protein begins.

Stat *Statim* (Latin); immediately.

Stationary phase Stage in the growth cycle of a bacterial culture in which the vegetative cell population equals the dying population.

STD Sexually transmitted disease.

Steatorrhea Excretion of large amounts of fat in the feces.

Sterile (sterility) Free of living microorganisms (the state of being sterile).

Sterilization Method that is capable of killing all life forms including endospores.

Stolon Horizontal stem of a plant or fungi that connects vertical growth of the organisms.

Stomatitis Inflammation of the mucous membranes of the oral cavity.

Stop codon A set of three nucleic acid bases on an mRNA that signals the termination of translation.

Strain typing Generally completed by molecular techniques to determine if an organism is identical to another organism or slightly different. Techniques include ribotyping, sequencing, Pulse Field Gel electrophoresis, and repetitive sequence-based PCR.

Streaking for isolation Technique used to separate microorganisms on artificial media to produce single isolated colonies from a single cell, to produce pure cultures or pure isolates for use in diagnostic testing.

Streptolysin O Oxygen-labile, immunogenic toxin produced by *Streptococcus pyogenes*, group A streptococci.

Streptolysin S Oxygen-stable, nonimmunogenic toxin produced by *Streptococcus pyogenes*, group A streptococci.

Stringency Condition that is described in molecular diagnostics that indicates a chemical and temperature environment that when high requires a specific match between two nucleic acid sequences close to 100%. Low stringency indicates a lower degree of complementation or match and allows flexibility in the interactions between two nucleic acid sequences.

Strobila Long chain of proglottids, or body of a tapeworm.

Struvite crystals Found in the urine of patients infected with ammonia-producing microorganisms. The crystals are composed of magnesium ammonium phosphate.

Stuart medium Semi-solid transport medium that minimizes growth of microorganisms while maintaining viability. Can be used for anaerobes and fastidious organisms such as *Neisseria* spp.

Subclinical Asymptomatic.

Subculture Passing a microorganism from a primary culture to additional artificial media for continued cultivation.

Substrate A substance on which an enzyme acts.

Substrate hyphae Filamentous structures that grow along the surface of the agar.

Substrate level phosphorylation The addition of a phosphate to an organic molecule, creating a high-energy bond that is processed during an intermediate step in a metabolic pathway.

Sulfur granule Small colony of organisms with surrounding clublike material; yellow-brown; resembles grain of sulfur.

Superantigen Molecules produced by microbes (viruses, bacteria, and perhaps parasites) that act independently to stimulate T-cell activities, including cytokine release. Among the most potent T-cell mitogens, superantigen stimulation can result in anergy, or alternatively, systemic immune system activation.

Superinfection Strictly speaking, superinfection refers to a new infection superimposed on another that is being treated with an antimicrobial agent. The new infecting agent is resistant to the therapy initially used and thus survives and causes persistence of the infection (now resistant to the treatment) or a new infection at a different site. The term is used to indicate persistence or colonization with a new organism without any evidence of resulting infection.

Superoxidized water (SOW) 144 mg/L of hypochlorous acid and chlorine, useful as an antiseptic or a disinfectant.

Suppuration Formation of pus.

Suppurative thrombophlebitis Inflammation of a vein wall.

Sympodial Branching of hyphae on two sides where one filament develops more strongly than the opposite. Branching is uneven as result.

Symptoms Something that is felt by an individual due to disease or illness that cannot be measured directly.

Synanamorph Fungi that have different asexual forms of the same fungus.

Syncytia Structure resulting from fusion of cell membranes of several cells to form a multinucleated cellular structure; usually the result of viral infection of the cells.

Syndrome Set of symptoms occurring together (e.g., nephrotic syndrome).

Synergism Combined effect of two or more drugs, such as antimicrobials, that is greater than the sum of their individual effects.

Synovial fluid Viscid fluid secreted by the synovial membrane; formed in joint cavities and bursa.

T

Tachypnea Rapid breathing.

Tachyzoite The trophozoite form of *Toxoplasma gondii* found in nerve and muscle tissue in the host.

TAE See tris-acetate buffer.

Taq polymerase Thermostable DNA polymerase that is used in PCR. Originally isolated from the microorganism *Thermus aquaticus.*

TBE See tris-borate buffer.

T cells (T lymphocytes) Lymphocytes involved in cellular immunity and activation of humoral immunity. Types of T cells include T helper, T suppressor, T regulatory, and cytotoxic T cells.

Target amplification Nucleic acid technique used to copy a specific gene or sequence logarithmically using PCR.

Tegument An asymmetric fibrouslike structure that surrounds the capsid of a virus and contains approximately 20 proteins. It is essential for initiation of viral replication.

Teichoic acids Glycerol or ribitol phosphate polymers combined with various sugars, amino acids, and amino sugars that are in the cell wall of gram-positive bacteria.

Teleomorph Sexual fungal form.

TEM Transmission electron micrograph.

Temperature enrichment Using a specific temperature that is either higher or lower than 37°C for the enhanced growth of a microorganism that is capable of growth above or below body temperature. This eliminates contaminating growth of organisms not capable of growth outside of normal body temperature. Used to cultivate most clinically relevant microorganisms.

Template Template strand of DNA that is copied into a complementary RNA during transcription.

Tenesmus Painful, unsuccessful straining in an attempt to empty the bowels due to a persistent feeling of needing to pass stool.

Therapy, antimicrobial Treatment of a patient to combat an infectious disease.

Thermal cycler A laboratory instrument that can be programmed to change temperatures; includes repeat cycling at specified times used to complete nucleic acid amplification reactions or PCR.

Thermolabile Adversely affected by heat (as opposed to thermostable, not affected by heat).

Thoracentesis Drainage of fluid from the pleural space.

Thoracic Pertaining to the chest cavity.

Threshold The portion of the curve in PCR where the signal begins to increase exponentially or logarithmically.

Threshold cycle (CT) The amplification cycle number in which the fluorescent signal rises above background by 10× the standard deviation of the baseline fluorescence; also referred to as the crossing point (CP) or cycle quantification (CQ).

Thrush A form of *Candida* infection that typically produces white plaquelike lesions in the oral cavity.

Time-kill studies Process used to determine the effectiveness of an antimicrobial agent or disinfectant that compares the amount of time required to slow the growth or kill the infectious agent.

Tinea Dermatophyte infection (tinea capitis, tinea of scalp; tinea corporis, tinea of the smooth skin of the body; tinea cruris, tinea of the groin; tinea pedis, tinea of the foot).

Tissue culture See cell culture.

Titer Level of a substance such as antibody or toxin present in material such as serum; reciprocal of the highest dilution at which the substance can still be detected.

T lymphocytes (T cells) Thymus-derived lymphocytes important in cell-mediated immunity.

Tm See melting temperature.

Tolerance A form of resistance to antimicrobial drugs; of uncertain clinical importance. See tolerant.

Tolerant Characteristic of an organism that requires a great deal more antimicrobial agent to kill it than to inhibit its growth.

Tonsillitis Inflammation of the tonsils.

Toxic shock syndrome A systemic disorder that may be fatal, caused by a bacterial toxin. It results in the release of biological mediators that result in low blood pressure, organ damage, and shock.

Toxins A chemical or protein that is produced by an animal, plant, fungi, or microorganism that can cause disease.

TPI *Treponema pallidum* immobilization test; a test for antibodies against the agent of syphilis that uses live treponemes.

Trichiasis Curling or ingrowth of eyelashes.

Trachoma Serious eye infection caused by *Chlamydia trachomatis*; often leads to blindness.

Transduction Moving genetic material from one prokaryote to another via a bacteriophage or viral vector.

Transformation (1) Process in which an organism takes up free DNA that is released into the environment when another organism dies and then lyses. (2) Process by which a virus changes a cell into a tumor or immortal cell line; a cancer-causing or transforming virus.

Transient bacteremia Incidental and brief presence of bacteria in the bloodstream.

Transient colonizers Microorganisms that are intermittently present on the surface of the human body or other animal. The organisms are capable of surviving for short periods on the surfaces but are unable to continue to multiply and reproduce for extended periods.

Transmission-based precautions Infection control guidelines used for patients known or suspected to be infected with pathogens spread by airborne or droplet transmission or by contact with dry skin or fomites.

Transposon Genetic material that can move from one genetic element to another (i.e., between plasmids or from a plasmid to a chromosome); so-called jumping genes.

Transposition The movement of a transposon from one genetic element to another.

Transtracheal aspiration Passage of needle and plastic catheter into the trachea to obtain lower respiratory tract secretions free of oral contamination.

Transudate Similar to exudate but with low protein content.

Trench fever Bacterial disease transmitted by lice.

Tris-acetate buffer (TAE) Used in nucleic acid separation techniques, fragments migrate more rapidly due to conductivity than in tris-borate buffer, resulting in better resolution with small fragments.

Tris-borate buffer (TBE) Used in nucleic acid separation techniques, fragments migrate more slowly than tris-acetate buffer, resulting in better resolution with larger fragments.

Trogocytosis The transfer of membrane fragments on an antigen-presenting cell to a lymphocyte.

Trophozoite Feeding, motile stage of protozoa.

Tropism Preferred environment or destination; attraction to. In viral infection, preference for a tissue site (rabies viruses have a tropism for neural tissue).

Trough level The lowest concentration for a drug or antibiotic in the bloodstream prior to the administering of another subsequent dose.

Trypomastigote Life cycle in flagellated protozoans with a flagellum extending externally on the posterior end of the organism.

TSI Triple sugar iron (agar tube).

TTA Transtracheal aspiration.

Tubercle Granuloma in the lung associated with *Mycobacterium tuberculosis* infection. See granuloma.

Tuberculoid leprosy Localized leprosy.

Tularemia Infectious disease caused by *Francisella tularensis.*

Turbidity Density of the organism present in the liquid medium; at least 106 bacteria per milliliter of broth are needed for turbidity to be detected with the unaided eye. A spectrophotometer may be used to measure the turbidity using the optical density (OD) of the culture.

Tympanocentesis Draining of fluid from the middle ear.

Type III secretion system Found in many gram-negative pathogens and is responsible for secretion and injection of virulence-associated factors into the cytoplasm of host cells.

Type IV secretion systems (bacterial) Bacterial devices that deliver macromolecular molecules such as proteins across and into cells.

Typhoid fever Bacterial infection caused by *Salmonella enterica* subsp. *enterica.*

Typing Methods of grouping organisms, primarily for epidemiologic purposes (e.g., biotyping, serotyping, bacteriophage typing, and the antibiogram).

Tzanck test Stained smear of cells from the base of a vesicle examined for inclusions produced by herpes simplex virus or varicella-zoster virus.

U

Umbilicate A bacterial or fungal colony demonstrating a depressed or sunken center.

Umbonate A bacterial or fungal colony demonstrating a raised center.

Undulating membrane Extension of the plasma membrane in protozoan flagellates that appears as a flap along the body for motility.

Uniserate Single row or layer.

Universal precautions See standard precautions.

Ureteritis Inflammation of the ureter.

Urethritis Inflammation of urethra, the canal through which urine is discharged (e.g., gonococcal urethritis).

Urosepsis Sepsis (systemic response to organisms in the bloodstream) caused by a urinary tract infection.

Urticarial Itchy, raised rash.

UTI Urinary tract infection.

V

Vaccination The process of administering a vaccine, which is generally a part of a microorganism or virus, or an attenuated bacterial toxin or microorganism that will activate the individual's immune response, resulting in the production of specific antibodies to the vaccine.

Variable regions The variable region of an antibody consists of the amino terminus of both the heavy and light chain proteins of the antibody. The regions have variable amino acid sequences that differ from one antibody to another, to enable the antibodies to bind to different antigens.

VD Venereal disease.

VDRL Venereal Disease Research Laboratory; classic nontreponemal serologic test for syphilis antibodies. Uses cardiolipin, lecithin, and cholesterol as cross-reactive antigen that flocculates in the presence of "reaginic" antibodies produced by patients with syphilis. Best test for cerebrospinal fluid in cases of neurosyphilis.

Vector An arthropod or other agent that carries microorganisms from one infected individual to another.

Vegetation In endocarditis, the aggregates of fibrin and microorganisms on the heart valves or other endocardium.

Vegetative hyphae Filamentous structures that grow down into the agar and draw nutrients from the agar substrate.

Vehicle See fomite.

Ventral disk Rigid protein structure on the ventral (underside) side of a parasite used for attachment to host cells.

Verrucose Furrowed or convoluted topology of a fungal colony.

Verruga Small bump on the skin or mucous membrane generally associated with a human papillomavirus.

Vesicle A small bulla or blister containing clear fluid.

V-factor See nicotinamide adenine dinucleotide (NAD).

Villi Minute, elongated projections from the surface of intestinal mucosa that are important in absorption.

Villose Soft hairlike.

Vincent angina An old term, seldom used currently, referring to anaerobic tonsillitis. Also referred to as acute necrotizing ulcerative gingivitis, or trench mouth.

Viral inclusions Nuclear or cytoplasmic inclusions that are clumps of proteins indicating viral replication inside the infected cell.

Viral neutralization The process where specific antibodies bind to the viral receptor molecule, blocking the virus's ability to bind with the host cell receptor and neutralizing the virus by preventing it from infecting the cell.

Viremia Presence of viruses in the bloodstream.

Virion The complete viral particle, including nucleocapsid, outer membrane or envelope, and all adherence structures.

Viroid Infectious naked RNA, single stranded with no protein coat. Primarily these infect plants.

Virulence Degree of pathogenicity or disease-producing ability of a microorganism.

Virulence factors Attributes or characteristics that enhance the organism's ability to invade or cause disease.

Virus Infectious agent that requires a living cell to reproduce.

Visceral Deep within tissue or organs (viscera).

Viscus (plural Viscera) Any of the organs (viscera) within one of the four great body cavities (cranium, thorax, abdomen, and pelvis).

Vitox Commercial supplement used in the preparation of Modified Thayer Martin or New York City Medium for the isolation of *Neisseria* spp.

VP Voges-Proskauer: a biochemical test that detects the presence of acetoin in bacterial cultures.

W

Wayson stain Special stain that uses basic fuchsin and methylene blue to identify the bipolar staining of *Yersinia pestis.*

Weil-Felix reaction Agglutination test for the diagnosis of rickettsia infections.

Western blot Proteins of an organism are separated by gel electrophoresis and transferred to membrane filters. Antiserum (labeled antibody) is allowed to react with the filters, and specific antibody bound to its homologous antigen is detected.

White piedra External fungal infection of hair that presents with soft nodules.

Wilkins-Chalgren agar Anaerobic agar for the isolation and identification of *Prevotella* spp.

Workup See identification scheme.

X

Xenodiagnosis Method of diagnosis infection by allowing the insect vectors to feed on the patient and then examine the vector for the infecting agent.

X-factor See hemin.

Z

Ziehl-Neelsen Traditional hot acid-fast method of staining organisms that contain muramic or mycolic acid.

Zone edge test Penicillin (10-U) disk test performed on Mueller-Hinton agar to determine whether the organism produces beta-lactamase. A sharp edge is considered positive and a fuzzy edge is considered negative.

Zone of equivalence Concentration when antigen and antibody are in equal concentrations resulting in maximum interactions and measurable cross-linking.

Zoonosis (zoonotic infection) A disease of animals (not human) transmissible to humans (e.g., tularemia).

Zoosporogenesis Reproduction of zoospores.

Zygomycetes Group of fungi with nonseptate hyphae and spores produced within a sporangium.

Zygospores Thick-walled diploid fungal cell that arises from the fusion of two haploid gametes.

    epidemiology and pathogenesis of, 846–849
    identification of, 853–856, 854f–856f
    pathogenesis and spectrum of disease, 849–850, 850t
  dermatophytes, 819–827
    characteristics of, 819–820
    epidemiology and pathogenesis of, 820
    laboratory diagnosis of, 821t, 822–827, 822f–827f
      Epidermophyton floccosum, 827, 827f
      Microsporum spp., 825–826, 826f
      Trichophyton spp., 822–827, 823f–825f
    spectrum of disease, 820–822
  general features of, 806–811, 810f–811f
  morphologic features of, 808–811, 810f–811f
  Mucorales, 815–819, 815f–817f
  opportunistic mycoses, 827–833, 828t, 830f–833f
  systemic mycoses, 833–843
    characteristics of, 834
    direct detection of, 836–840, 836f–839f
    epidemiology of, 834–835
    identification of, 840–843, 841f–843f
    pathogenesis and spectrum of disease, 835–836
    serodiagnosis of, 843
Molecular beacon, 133–134
Molecular beacon in real-time polymerase chain reaction, 135f
Molecular methods, for fungal identification, 801
Molecular sequencing of viruses, 900
Molecular siblings, 792–793
Molecular weight-size markers, 131
Moniliform hyphae, 851
Monoclonal antibodies, 153–154, 154f
Monocytes, 33–34
Monolayer (single confluent layer) virus, 909–910
Monomicrobic aggregation, 40
Monotrichous flagella, 24
Monoxenic, 637
Monoxenic culture method, 637
Monozoic tissue cysts, 677
Moraxella catarrhalis
  antimicrobial susceptibility testing and therapy for, 503
  case study of, 504.e1b
  characteristics of, 419, 495
  cultivation of, 499–500, 500t
  direct detection of, 498–499
Moraxella catarrhalis (Continued)
  epidemiology of, 496, 496t
  identification of, 215b, 222b, 500–503, 501t
  pathogenesis and spectrum of disease, 496, 497t
  specimen processing of, 498
Moraxella spp., 419–424.e1
  case study of, 424.e1b
  characteristics of, 419
  epidemiology, spectrum of disease, and antimicrobial therapy, 419–420, 420t
  laboratory diagnosis of, 420–423
  prevention of, 423
  specimen processing of, 420, 421t–422t
Morbidity rate, 27b
Mordant, 81
Morganella spp., 343
  colonial appearance of, 352t–353t
